- Most of those who are going to get polyps will have them at 20 years, and these require operation.
- If there are no polyps at 20 years, continue with five-yearly examination until age 50 years; if there are still no polyps, there is probably no inherited gene. Carcinomatous change may exceptionally occur before the age of 20 years. Examination of blood relatives, including cousins, nephews and nieces, is essential, and a family tree should be constructed and a register of affected families maintained. Referral to a medical geneticist is essential.

Treatment

The aim of surgery is to prevent the development of colorectal cancer. The surgical options are:

- colectomy with ileorectal anastomosis (IRA);
- restorative proctocolectomy (RPC) with an ileal pouch-anal anastomosis, the anastomosis may be defunctioned with a loop ileostomy;
- total proctectomy and end ileostomy (normally reserved for patients with a low rectal cancer).

The patient is almost always young and likely to prefer to avoid a permanent stoma and so the choice is normally between the first two options. The advantage of an IRA is that it avoids the temporary stoma frequently required for an RPC and avoids the potential compromise to sexual function that accompanies proctectomy. It also has a lower morbidity and mortality. However, the rectum is left and requires regular surveillance, as there is a risk of adenomas and carcinomas in the residual large bowel. Even with optimal surveillance of the rectal remnant, up to 10 per cent will develop invasive malignancy within a 30-year follow-up period. Restorative proctocolectomy has the advantage of removing the whole colon and rectum (although a small cuff of rectal mucosa may be left behind with a stapled anastomosis). However, there is a pouch failure rate of about 10 per cent. In addition, and particularly where a stapled anastomosis has been created, there remains a very small but definite incidence of cancer developing in the small strip of rectal mucosa between the pouch and the dentate line. This is why some colorectal surgeons advocate complete mucosectomy of the residual rectal cuff and a transanal pouch anal anastomosis, although it is acknowledged that this results in worse function.

Postoperative surveillance

Because of the risk of further tumour formation, follow up is important and takes the form of rectal/pouch surveillance, with biopsy of the pouch-anal anastomosis. Gastroscopies are also carried out to detect upper gastrointestinal tumours. Even with prevention of colorectal cancer, FAP patients have reduced life span due to the development of duodenal and ampullary cancers and the complications of desmoid tumours.

Hereditary non-polyposis colorectal cancer (Lynch syndrome)

This syndrome is characterised by increased risk of colorectal cancer and also cancers of the endometrium, ovary, stomach and small intestines. It is an autosomal dominant condition that is caused by a mutation in one of the DNA mismatch repair genes. The most commonly affected genes are MLH1 and MSH2. The lifetime risk of developing colorectal cancer in Lynch syndrome is 80 per cent, and the mean age of diagnosis is 45 years. Most cancers develop in the proximal colon. Females with HNPCC have a 30–50 per cent lifetime risk of developing endometrial cancer.
Diagnosis

HNPCC can be diagnosed by genetic testing or the Amsterdam II criteria:

- three or more family members with an HNPCC-related cancer (colorectal, endometrial, small bowel, ureter, renal pelvis), one of whom is a first-degree relative of the other two;
- two successive affected generations;
- at least one colorectal cancer diagnosed before the age of 50 years;
- FAP excluded;
- tumours verified by pathological examination.

Patients with HNPCC are subjected to regular (every one to two years) colonoscopic surveillance.

Malignant

Epidemiology

In the UK, colorectal cancer is the second most common cause of cancer death accounting for 16,000 deaths in 2004. About 35,000 patients are diagnosed with colorectal cancer every year in the UK, of which around one-third are in the rectum and two-thirds in the colon. The burden of disease is similar in men and women. Colorectal cancer seems to occur less frequently in the developing world than in industrialised countries.

Aetiology

The accepted model of colorectal cancer development is that it arises from adenomatous polyps after a sequence of genetic mutations influenced by environmental factors. This adenoma–carcinoma sequence is based on strong observational evidence outlined in Summary box 69.11.

Summary box 69.11

Evidence for adenoma–carcinoma sequence

- The prevalence of adenomas and carcinomas is very similar – carcinoma patients are about five years older
- The distribution of adenomas in the colon is the same as that of cancers (70 per cent left sided)
- When small cancers are studied, they almost always have adjacent adenomatous tissue
- Adenomas are found in a third of specimens resected for colorectal cancer
- Sporadic adenomas are identical to the adenomas of familial adenomatous polyposis, which is associated with a 100 per cent chance of colorectal adenocarcinoma unless treated
- Larger adenomas are more likely to be dysplastic and to have higher grades of dysplasia than small adenomas
- Incidence of colorectal cancer falls within a screening programme that involves colonoscopy and polypectomy

The molecular genetics of sporadic colorectal cancer have been extensively studied. Mutations of the APC gene occur in two-thirds of colonic adenomas and carcinomas and are thought to develop early in the carcinogenesis pathway. K-ras mutations result in activation of cell signalling pathways and are more common in larger lesions. This suggests that they are later events in the mutagenesis pathway. The p53 gene is frequently mutated in carcinomas, but not in adenomas and is therefore thought to mark the development of invasion. The adenoma–carcinoma sequence is not, however, one of a simple stepwise progression of mutations, but a complicated array of multiple genetic alterations, ultimately resulting in an invasive tumour. While no single mutation is common to all cases of colorectal cancer, knowledge of certain mutations can be used to assess prognosis and, increasingly to direct adjuvant therapy. For example, the K-ras mutation is thought to be associated with an especially poor prognosis.

There has been much interest in the linkage between diet and colon cancer. Worldwide, the prevalence of colorectal cancer is closely associated with intake of red meat. There is ample evidence to suggest effects of red meat components (haem and N-nitroso compounds) on the DNA in the colorectal mucosa. The protective effect of dietary fibre is also suggested by epidemiological studies. The hypothesis is that increased roughage is associated with reduced transit times, and this in turn reduces the exposure of the mucosa to dietary carcinogens. Increased risk for colorectal cancer has also been associated with dietary animal fat, smoking and alcohol. Longstanding ulcerative colitis and Crohn’s colitis is associated with increased rates of colorectal cancer as discussed previously. It has been suggested that cholecystectomy may be associated with a slight increase in the risk of right-sided colon cancer, possibly as a consequence of increased bile acid exposure. There is also an increased risk of colorectal cancer after ureterosigmoidostomy, although this procedure is now rarely performed.

Pathology

Macroscopically, the tumour may take one of four forms (Figure 69.22). The annular variety tends to give rise to obstructive symptoms, whereas the others will present more commonly with...
bleeding. Microscopically, the neoplasm is an adenocarcinoma originating in the colonic epithelium.

**SPREAD OF CARCINOMA OF THE COLON**

**Direct spread**
Colonic cancer can spread locally or via the lymphatics, bloodstream or transcoelomically around the peritoneum. Direct spread can be longitudinal, transverse or radial. Radial spread to adjacent organs has the greatest impact on surgical resectability, as an adequate oncologic resection can still be achieved, despite longitudinal spread, by extension of proximal and distal margins. Radial spread may be retroperitoneal into the ureter, duodenum and posterior abdominal wall muscles, or intraperitoneal into the small intestine, stomach, pelvic organs or the anterior abdominal wall.

**Lymphatic spread**
In general, involvement of the lymph nodes by the tumour progresses in a gradual manner from those closest to the bowel along the course of the lymphatic vessels to those placed centrally. However, this orderly process does not always occur.

**Haematogenous spread**
The liver accounts for the majority of distant metastases presumably via the portal vein. Around a third of patients will have liver metastases at the time of diagnosis and 50 per cent will develop liver metastases at some point accounting for the majority of deaths. The lung is the next most common site: metastases to ovary, brain, kidney, brain and bone are less common. Occasionally, patients will present with metastatic disease in the lungs without evidence of liver metastases.

**Transcoelomic spread**
Colorectal cancer can spread by way of cells dislodging from the serosa of the bowel or via the subperitoneal lymphatics and settling on other structures within the peritoneal cavity, including peritoneum and omentum. Prognosis is typically grave in these circumstances although some units have reported encouraging results in selected patients treated with the combination of aggressive cytoreductive surgery and intraperitoneal chemotherapy.

**Staging colon cancer**
A variety of staging systems are described for colorectal cancer based on pathological reporting to predict prognosis and guide adjuvant treatment. Dukes’ classification was originally described for rectal tumours (see Chapter 72), but has been adopted for histopathological reporting of colon cancer as well. It is simple and widely recognised (Summary box 69.12), but the more detailed TNM system is now regarded as the international standard (Summary box 69.13).

**Clinical features**
Carcinoma of the colon typically occurs in patients over 50 years of age and is most common in the eighth decade of life. Colorectal cancer is not rare in early adult life, however. Twenty per cent of cases present as an emergency with intestinal obstruction or peritonitis. An emergency presentation of colorectal cancer is, even when matched for disease stage, associated with a considerably worse prognosis. A careful family history should be taken. Those with first-degree relatives who have developed colorectal cancer at the age of 45 years or below are at higher risk and may be part of one of the colorectal cancer familial syndromes. Tumours of the left side of the colon which are far more common (Figure 69.23) usually present with a change in bowel habit or rectal bleeding, while more proximal lesions typically present later with iron deficiency anaemia or a mass. Patients may present for the first time with metastatic disease. Lesions of the flexures may present with vague upper abdominal symptoms for many months before other, more specific symptoms suggestive of colonic disease appear.

---

Rupert B Turnbull, 1913–1981, Irish surgeon, Cleveland Clinic, Ohio, reported the presence of cancer cells in the portal vein of patients undergoing resection for colon cancer. He then described in his Moynihan lecture a ‘no touch’ isolation technique to reduce the manipulation of colonic tumours at surgery.

Cothbert Esquire Dukes, 1890–1977, pathologist, St Mark’s Hospital, London, UK. The original Dukes’ classification in 1932 gave three stages, A–C.
Investigation of colon cancer

Screening

Colon cancer is highly suited to screening as prognosis is better for early stage disease and polypectomy allows the prevention of cancer development. In the UK, a screening programme has been introduced based on faecal occult blood testing of people aged 60–69 years followed by colonoscopy in those who test positive. A guaiac-based test is used which detects the peroxidase-like activity of faecal haematin. Studies have suggested a 15–20 per cent reduction in colorectal cancer mortality in the screened population. Flexible sigmoidoscopy can also be used as the initial screening tool with a similar reduction in colorectal cancer mortality.

Endoscopy

The 60-cm, fibreoptic, flexible sigmoidoscope is increasingly being used in one-stop rectal bleeding clinics. The patient is prepared with an enema and sedation is not usually necessary. It is usually possible to assess the bowel up to the splenic flexure, which will detect up to 70 per cent of cancers and almost all that cause rectal bleeding. Colonoscopy is the investigation of choice if colorectal cancer is suspected, provided the patient is fit enough to undergo the required mechanical bowel preparation (Figure 69.24). It has the advantage of not only picking up a primary cancer, but also having the ability to detect synchronous polyps or even multiple carcinomas, which occur in 3–5 per cent of cases. Ideally, every case should be proven histologically by biopsy before surgery. Full mechanical bowel preparation is necessary, as well as intravenous sedation. There is a small risk of perforation (1:1000) and also even experienced endoscopists may fail to see the caecum in 10 per cent of cases.

Radiology

Double-contrast barium enema shows a cancer of the colon as a constant irregular filling defect often described as looking like an apple core (Figure 69.25). False positives occur in 1–2 per cent of cases and false negatives in 7–9 per cent of cases. CT is used as a diagnostic tool in patients with palpable abdominal masses. Use of spiral CT of the chest and abdomen is now standard to stage colonic cancer by assessing T stage and detecting metastases although chest x-ray and liver ultrasound are an alternative if CT is not readily available. The introduction of CT virtual colonoscopy, which is effective in picking up polyps down to 6 mm (Figure 69.26) provides another diagnostic modality and has largely replaced barium enema in many centres. It has the advantage of being less invasive than colonoscopy, but if a biopsy is required, an endoscopy will still be needed.

Surgical treatment

Preoperative preparation

There is good evidence that there is no benefit for mechanical bowel preparation in colonic cancer surgery and it may in fact be associated with an increased rate of wound infection. Rectal cancer seems to be different and recent trials suggest that mechanical bowel preparation is probably still appropriate. Thromboembolism is common in general surgical patients and the risk is increased by malignant disease, so antiembolic stockings should be fitted and the patient started on prophylactic low molecular weight heparin. If available, manual compression boots can be used perioperatively. Intravenous prophylactic antibiotics are given at the start of surgery, as there is good evidence that these reduce the risk of
would infection and sepsis. A single dose of antibiotics covering bowel organisms is as effective as multiple doses in preventing wound infection. In all cases where a stoma seems likely, careful preoperative counselling and marking of an appropriate site by an enterostomal therapist is essential.

**Operations**

The operations described are designed to remove the primary tumour and its draining locoregional lymph nodes. After spiral CT, it is unusual to find unsuspected metastases at laparotomy (or laparoscopy), but the presence of peritoneal metastases may predicate a palliative strategy with a segmental resection and less aggressive lymphadenectomy. The use of stapling and hand-suturing techniques for colonic anastomosis has been compared, and there is little difference in leak rate between the two. Recurrent disease does occur typically at the anastomosis and re-resection can be successful.

**Right hemicolecotomy**

Carcinoma of the caecum or ascending colon (Figure 69.27) is treated when resectable by right hemicolecotomy (Figure 69.28). At open surgery, the peritoneum lateral to the ascending colon is incised, and the incision is continued around the hepatic flexure. The right colon is elevated, with the leaf of peritoneum containing its vessels and lymph nodes, from the posterior abdominal wall, taking care not to injure the ureter, gonadal vessels or the duodenum. The ileocolic artery is ligated close to its origin off the superior mesenteric artery ("high-tie") and divided. Where the right colic artery has a separate origin from the superior mesenteric artery (around 10 per cent of patients), this is separately ligated. The leaf of raised peritoneum attached to the caecum, ascending colon and hepatic flexure is divided after ligation of the mesentery of the last 20 cm of ileum and the mesocolon as far as the proximal third of the transverse colon. The greater omentum is divided up to the point of intended division of the transverse colon. When it is clear that there is an adequate blood supply at the resection margins, the right colon is resected, and an anastomosis is fashioned between the ileum and the transverse colon using the surgeon’s preferred technique. If the tumour is at the hepatic flexure, the resection must be extended further along the transverse colon and will involve dividing the right branch of the middle colic artery.
Extended right hemicolecotomy
Carcinomas of the transverse colon and splenic flexure are most commonly treated by an extended right hemicolecotomy. The extent of the resection is from right colon to descending colon. The mobilisation is as for a right hemicolecotomy, but dissection continues to take down the splenic flexure and the whole transverse mesocolon is ligated. Some surgeons will perform a left hemicolecotomy for a splenic flexure cancer.

Left hemicolecotomy
This is the operation of choice for descending colon and sigmoid cancers (Figure 69.29). The left half of the colon is mobilised completely along the ‘white line’ that marks the lateral attachment of the mesocolon. As the sigmoid mesentery is mobilised, the left ureter and gonadals must be identified and protected. The splenic flexure must be mobilised by extending the dissection from below and from the transverse colon side by entering the lesser sac. The inferior mesenteric artery below its left colic branch, together with the related paracolic lymph nodes, are included in the resection by ligating the inferior mesenteric artery close to its origin – ‘high-tie’. For full mobility, the inferior mesenteric vein is also ligated and divided at the lower border of the pancreas. The bowel and mesentery can now be resected to allow a tension-free anastomosis, which can be stapled with an end–end stapling device or hand-sewn. Where there are technical difficulties or concern about the anastomosis, a temporary diverting stoma may be fashioned upstream, usually by formation of a loop ileostomy.

Laparoscopic surgery
Laparoscopic surgery for colonic cancer has now been shown to have equivalent overall and cancer-related outcomes to open surgery. Lymph node harvests are equivalent to open surgery and initial concerns about reports of port site recurrence have been dispelled as the world experience has grown. In the UK, the National Institute for Health and Clinical Excellence (NICE) has endorsed laparoscopic colorectal surgery and has stated it should be offered to suitable patients. Operative times are longer but wound infection rates, blood loss and postoperative pain scores are lower than for open surgery. It is hoped that these factors will lead to shorter hospital stay and faster return to full activity, but this has yet to be firmly demonstrated. The costs of laparoscopic surgery are generally higher and this may be particularly relevant where funds are limited.

It is not possible to palpate lesions, so if laparoscopic surgery is planned, it is ideal to tattoo the lesion. Different surgeons advocate different port positions. The laparoscopic operation has particular advantages if performed in a medial to lateral manner – that is, starting the dissection by controlling and dividing the major vascular pedicles and only taking the lateral peritoneal reflection once the mesocolon is completely free. Specimen retrieval and bowel anastomosis can then be performed via small incisions. Training in laparoscopic surgery is important, as there is a steep learning curve and in the UK is currently part of a national training programme.

Emergency surgery
In the UK, 20 per cent of patients with colonic cancer will present as an emergency, the majority with obstruction, but occasionally with haemorrhage or perforation. If the lesion is right sided, it is usually possible to perform a right hemicolecotomy and anastomosis in the usual manner; this can be facilitated by decompressing the bowel at the start of the operation. If there has been perforation with substantial contamination or if the patient is unstable, it may be advisable to bring out an ileostomy rather than anastomosing bowel in these circumstances. For a left-sided lesion, the decision-making process is similar to that in diverticular disease between a Hartmann’s procedure and resection and anastomosis. Where facilities are present, an obstructing left-sided lesion can be treated with an expanding metal stent (Figure 69.30). This has the great advantage of converting an emergency operation with a high chance of a stoma to a situation which can be managed semi-electively with a resection and anastomosis. It is currently unclear whether

Figure 69.29 Schematic showing left hemicolecotomy.

Figure 69.30 Abdominal radiograph demonstrating a colonic stent in position (courtesy of Dr D Kasir, Hope Hospital, Salford, UK).
the overall morbidity and mortality of staged management of an obstructing colorectal cancer by initial stenting and later surgery are lower than primary emergency surgery. Results from two European trials have so far failed to demonstrate a benefit and the patients in whom stenting proved impossible seemed to have a higher morbidity and mortality, possibly because of the inherent delay in undertaking definitive surgical treatment. A larger multicentre trial is currently in progress.

**Postoperative care**

After colonic surgery, patients should be closely monitored, as there is a small incidence of postoperative bleeding. Antithrombosis measures prophylaxis against venous thromboembolism should be continued as discussed above under Preoperative preparation. There is no advantage to placing intra-abdominal drains after colonic surgery. Wound infections are sadly common after colonic surgery and may well be more frequent than the quoted 10 per cent. The most feared postoperative complication of anastomotic breakdown or leak occurs in 4–8 per cent of ileocolic or colocolic anastomoses. It should be kept in mind for any patient not progressing as expected or who is developing temperatures and worsening abdominal pain. Early investigation with contrast-enhanced CT scan is appropriate. In the presence of sepsis or peritonitis, early return to theatre and taking down the leaking anastomosis with the formation of stomas is advised.

Traditional practices after bowel surgery were prolonged nasogastric drainage and very cautious introduction of oral fluid and then diet. There is increasing interest after bowel surgery in enhanced recovery programmes (ERPs) which have been shown to reduce length of hospital stay from the traditional 10–14 days, to as little as 2–3 days by modulating the surgical stress response and reducing postoperative ileus. It is important to appreciate that these programmes require multiple interventions to be instituted and considerable time, effort and education from the surgical, anaesthetic and ward teams (Summary box 69.14).

**Summary box 69.14**

**Key elements of an enhanced recovery programme**

- Pre-admission counselling
- Avoidance of mechanical bowel preparation
- Preoperative carbohydrate loading
- Avoidance of preoperative dehydration
- No nasogastric tubes
- Short, transverse incisions (or laparoscopic procedure)
- Short-acting anaesthetic drugs
- Avoidance of perioperative fluid/salt overload
- Thoracic epidurals
- Avoidance of opiate analgesia
- Maintenance of perioperative temperature
- Prevention of postoperative nausea and vomiting
- Early mobilisation
- Early introduction of oral fluids/diets/supplements
- Early removal of urinary catheters
- Continual audit of outcomes

**Adjuvant therapy**

This is discussed in more detail in Chapter 72 under rectal cancer. In colonic cancer, there is no current role for preoperative chemotherapy although a trial is underway. There is evidence of improved outcome after surgery with 5-fluorouracil (5-FU)-based chemotherapy in node-positive disease (Dukes' C/N1,2).

**Metastatic disease**

Hepatic metastases can be resected and series have demonstrated five-year survival of over 30 per cent in resectable disease. Liver surgeons are increasingly aggressive in treatment and the only absolute limitation on what can be resected is in terms of leaving enough functional liver behind, although this clearly has to be moderated in terms of patient factors. It is important not to biopsy potentially resectable hepatic metastases as this may cause tumour dissemination. Imaging will usually correctly identify colorectal metastases and assess patients' suitability for liver resection (Figure 69.31). The role of chemotherapy and the timing of colonic and hepatic surgery in synchronous metastases is still a matter of debate and such cases should be carefully discussed by a multidisciplinary team. Isolated lung metastases may also in occasional cases be suitable for resection, but generally they are accompanied by metastases elsewhere. In patients with widespread disease, palliative chemotherapy can be offered alongside symptomatic treatment and support by a palliative care team.

**Prognosis**

Overall five-year survival for colorectal cancer is approximately 50 per cent. The most important determinant of prognosis is tumour stage and, in particular, lymph node status. Patients with disease confined to the bowel wall (Dukes’ stage A) will
usually be cured by surgical resection alone and 90 per cent of such patients will have disease-free survival at five years. Spread beyond the bowel wall reduces five-year survival to approximately 60–70 per cent. Patients with lymph node metastases have a five-year survival of 30 per cent, while fewer than 10 per cent of patients presenting with metastatic disease at outset will be alive five years later.

Colorectal cancer follow up
Since the advent of safe liver resection for metastases, the outcome benefit of follow up has become evident and has been demonstrated by meta-analysis. Follow up aims to identify synchronous bowel tumours that were not picked up at original diagnosis due to emergency presentation or incomplete assessment (3 per cent of patients will have a second bowel cancer at diagnosis). Similarly, 3 per cent of patients will develop a metachronous (at a different time) colonic cancer and surveillance colonoscopy is designed to diagnose these. Up to a half of patients with colorectal cancer will have liver metastases at some point and regular imaging of the liver (ultrasound and CT scan) and measurement of carcinoembryonic antigen (CEA) is designed to diagnose this early, in order to allow the possibility of curative metastectomy. Trials of the optimum follow-up pathway are ongoing.

INTESTINAL DIVERTICULA
Diverticula (hollow out-pouchings) are a common structural abnormality that can occur from the oesophagus to the rectosigmoid junction (but not usually in the rectum). They can be classified as:

- **Congenital.** All three coats of the bowel are present in the wall of the diverticulum, e.g. Meckel’s diverticulum.
- **Acquired.** There is no muscularis layer present in the diverticulum, e.g. sigmoid diverticula.

Jejunal diverticula
These arise from the mesenteric side of the bowel as a result of mucosal herniation at the point of entry of the blood vessels. They can vary in size and are often multiple. They are most often asymptomatic and an incidental finding at surgery or on radiological imaging (Figure 69.32); however, they can result in malabsorption, as a result of bacterial stasis, or present as an acute abdominal emergency if they become inflamed or perforate. Bleeding from a jejunal diverticulum is a rare complication. Elective resection of an affected small bowel segment that is causing malabsorption can be effective. If perforated jejunal diverticulitis is found at emergency laparotomy, a small bowel resection should be performed and a decision made between anastomosis and stoma formation. This will depend on degree of contamination, physiological stability and local resource for managing a patient with a high output jejunostomy. Extensive jejunal diverticulosis can be very difficult to treat. In severe cases, much of the proximal small intestine may be involved, effectively precluding resection. In addition, limited resection, while feasible, may fail to deal adequately with recurrent attacks of inflammation or bleeding.

Meckel’s diverticulum
A Meckel’s diverticulum is a persistent remnant of the vitellointestinal duct and is present in about 2 per cent of the population. It is found on the antimesenteric side of the ileum, commonly at 60 cm from the ileocaecal valve and is classically 5 cm long (Figure 69.33). A Meckel’s diverticulum contains all three coats of the bowel wall and has its own blood supply. It is vulnerable to obstruction and inflammation in the same way as the appendix; indeed, when a normal appendix is found at surgery for suspected appendicitis, a Meckel’s diverticulum should be looked for by examining the small bowel particularly if free fluid or pus is found (Summary box 69.15).

Figure 69.33 Meckel’s diverticulum.

Johann Friedrich Meckel (the younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany, described the diverticulum in 1809.
In around 20 per cent of cases, the mucosa of a Meckel's diverticulum contains heterotopic epithelium of gastric, colonic or pancreatic type. A Meckel's diverticulum can present clinically in the following ways:

- **Haemorrhage.** If gastric mucosa is present, peptic ulceration can occur and present as painless maroon rectal bleeding or melaena. If the stomach, duodenum and colon are cleared by endoscopy, radioisotope scanning with technetium-99m may demonstrate a Meckel's. (A Meckel's is notoriously difficult to see with contrast radiology.)
- **Diverticulitis.** Meckel's diverticulitis presents like appendicitis, although if perforation occurs the presentation may resemble a perforated duodenal ulcer.
- **Intussusception.** A Meckel's can be the lead point for ileoileal or ileocolic intussusception.
- **Chronic ulceration.** Pain is felt around the umbilicus, as the site of the diverticulum is midgut in origin.
- **Intestinal obstruction.** A band between the apex of the diverticulum and the umbilicus (also part of the vitellointestinal duct) may cause obstruction directly or by a volvulus around it.
- **Perforation.** (Figure 69.34).

The vast majority of Meckel's are asymptomatic. When found in the course of abdominal surgery, a Meckel's can safely be left alone provided it has a wide mouth and is not thickened. When there is doubt, it can be resected. The finding of a Meckel's diverticulum in an inguinal or femoral hernia has been described as Littre's hernia.

### Meckel's diverticulectomy

A broad-based Meckel's diverticulum should not be amputated at its base and invaginated (as for an appendix), as there is the risk of stricture and of leaving heterotopic epithelium behind. It is safer simply to excise the diverticulum, either by resecting it and suturing the defect at its base, or with a linear stapler-cutter. If the base of the diverticulum is indurated, it is on balance more logical to perform a limited small bowel resection of the involved segment followed by an anastomosis.

### Diverticular disease of the large intestine

Diverticula are found in the left colon in around 75 per cent of over 70 year olds in the Western world. The condition is overwhelmingly found in the sigmoid, but diverticula are found in the caecum and can affect the whole colon (but not the rectum). Interestingly, in South-East Asia, right-sided diverticular disease is more common. Diverticula are most often asymptomatic (diverticulosis) and found incidentally, but can present clinically with sepsis or haemorrhage.

### Aetiology

Epidemiology supports the widely held view that diverticular disease is a consequence of a refined Western diet deficient in dietary fibre. The combination of altered collagen structure with ageing, disordered motility and increased intraluminal pressure most notably in the narrow sigmoid colon results in herniation of mucosa, protruding through the circular muscle at the points where blood vessels penetrate the bowel wall. The rectum has a complete muscular coat and a wider lumen and is thus very rarely affected. Diverticular disease is rare in Africa and Asia where the diet is high in natural fibre.

### Complications of diverticular disease

The majority of patients with diverticula are asymptomatic; historical studies suggest somewhere between 10 and 30 per cent will have symptomatic complications (Summary box 69.16). These complications are:

- **Pain and inflammation** (diverticulitis).
- **Perforation:** most often contained leading to pericolic abscess formation, but occasionally free leading to generalised peritonitis.
- **Intestinal obstruction:** progressive fibrosis can cause stenosis of the sigmoid and large bowel obstruction or loops of small intestine can adhere to an inflamed sigmoid resulting in small bowel obstruction.
- **Haemorrhage:** diverticulitis may present with profuse colonic haemorrhage.
- **Fistula formation:** (colovesical, colovaginal, enterocolic, colocutaneous) occurs in 5 per cent of cases, colovesical fistulation is most common.
PART 11
ABDOMINAL

Intestinal diverticula

Summary box 69.16
Complications of diverticular disease
- Diverticulitis
- Abscess
- Peritonitis
- Intestinal obstruction
- Haemorrhage
- Fistula formation

Clinical features
In mild cases, symptoms such as distension, flatulence and a sensation of heaviness in the lower abdomen may be indistinguishable from those of irritable bowel syndrome. These symptoms are thought to result from a combination of increased luminal pressure affecting wall tension and increased visceral hypersensitivity. The difficulty in distinguishing between otherwise uncomplicated diverticular disease and irritable bowel syndrome is such that surgical treatment is rarely, if ever, appropriate for diverticular disease in the absence of complications.

Diverticulitis typically presents as persistent lower abdominal pain, usually in the left iliac fossa accompanied by loose stools or indeed constipation. Fever, malaise and leukocytosis can differentiate diverticulitis from painful diverticulosis. The lower abdomen is tender, especially on the left, but occasionally also in the right iliac fossa, if the sigmoid loop lies across the midline. The sigmoid colon may be tender and thickened on palpation and rectal examination may reveal a tender mass if an abscess has formed. Distinguishing between diverticulitis and abscess formation is difficult on clinical grounds alone and radiological imaging assessment is important. Generalised peritonitis as a result of free perforation presents in the typical manner with systemic upset and generalised tenderness, guarding and rebound. Similarly, large and/or small bowel obstruction due to diverticular disease has the same clinical features as other causes (see Chapter 69) and the aetiology is likely to be discovered only by imaging or at laparotomy.

Haemorrhage from colonic diverticula is typically painless and profuse. When from the sigmoid, it will be bright red with clots, whereas right-sided bleeding will be darker. Torrential bleeding is fortunately rare and in fact more commonly due to angiodysplasia but diverticular bleeding may persist or recur requiring transfusion and indeed resection. The presentation of a fistula resulting from diverticular disease depends on the site. The most common colorectal fistula results in recurrent urinary tract infections and pneumaturia (flatus in the urine) or even faeces in the urine. Colovaginal fistulae are more common in patients who have had a hysterectomy. Colocutaneous fistulae are rare in the absence of prior intervention (e.g., radiological drainage). Rarely, diverticular disease may perforate into the retroperitoneum leading to a psoas abscess, and then presenting in the groin with fistulation.

Classification of contamination
The degree of sepsis has a major impact on outcome in acute diverticulitis. Those with inflammatory masses have a lower mortality than those with perforation (3 versus 33 per cent).

Classification systems have been developed for acute diverticulitis to try and rationalise the literature, the most commonly used is the Hinchey classification (Table 69.3).

Table 69.3 Hinchey classification of complicated diverticulitis.

Radiology
Plain chest and abdominal radiographs can demonstrate a pneumoperitoneum. Where available, spiral CT has excellent sensitivity and specificity for identifying bowel wall thickening, abscess formation and extraluminal disease and has revolutionised the assessment of complicated diverticular disease (Figure 69.35). On identification of abscesses in stable patients, drainage may be carried out percutaneously, avoiding the need for laparotomy/laparoscopy. If access to CT is limited, a watersoluble contrast enema can demonstrate intraluminal inflammation and contrast extravasation. This investigation also has a role in large bowel obstruction to distinguish mechanical blockage from pseudo-obstruction, however distinguishing between a malignant and a diverticular stricture may be difficult.

Barium enemas (and colonoscopy/flexible sigmoidoscopy) are usually avoided in the acute setting for fear of causing perforation or peritonitis. However, they are used after an attack has settled to exclude a coexisting carcinoma and assess

Figure 69.35 Computed tomographic scan demonstrating an abscess associated with diverticulitis (courtesy of Dr D Kasir, Hope Hospital, Salford, UK).
the extent of diverticular disease (Figure 69.36). Colovesical fistulae should be evaluated with cystoscopy and biopsy in addition. Contrast examinations or CT may demonstrate the fistula clearly. The differential diagnosis for colovesical fistula includes cancer, radiation injury, Crohn’s disease, tuberculosis and actinomycosis.

**Colonoscopy**

Colonoscopy is normally deferred until 6 weeks after an acute attack of diverticulitis. It may demonstrate the necks of diverticula within the bowel lumen (Figure 69.37). A narrowed area of diverticular disease may be impassable because of the severity of disease and there is a significant risk of endoscopic perforation. Colonoscopy in these circumstances requires judgement and experience. The differential diagnosis from a carcinoma can be impossible if a tight stenosis prevents colonoscopy. Biopsies may be taken if possible and corroborated with barium enema or CT virtual colonoscopy is required.

**Management**

Patients are frequently recommended to take a high-fibre diet and bulk-forming laxatives, although the evidence for the effectiveness of these in diverticulosis or after an attack of diverticulitis is limited. Antispasmodics may have a role if recurrent pain is a problem. Acute diverticulitis is treated by intravenous antibiotics (to cover Gram-negative bacilli and anaerobes) alongside appropriate resuscitation and analgesia. Nil by mouth to ‘rest the bowel’ and catheterisation to reduce the risk of colovesical fistulation are often advocated, but there is little evidence to support these practices. A CT scan can confirm the diagnosis and assess for complications. After the acute attack has subsided and if CT has not already confirmed the diagnosis, the bowel should be investigated by endoscopy, barium enema or CT virtual colonoscopy. An abscess can be drained percutaneously, 5 cm is frequently regarded as a cut off between an abscess likely to settle with antibiotics and one likely to require intervention.

**Operative procedures for diverticular disease**

The aim of emergency surgery is to control peritoneal sepsis; indications are generalised peritonitis and failure to respond to best medical management (Summary box 69.17). Laparotomy for diverticular disease in the acute setting has considerable risk with mortality in most series around 15 per cent and in the case of faecal peritonitis mortality approaches 50 per cent. Alongside operative technique, resuscitation, anaesthesia and postoperative management should be optimised.

It is logical to perform a rigid sigmoidoscopy to avoid missing a rectal carcinoma. Laparotomy and thorough washout of contamination are performed and then a choice has to be made between a Hartmann’s procedure (sigmoid resection with formation of left iliac fossa colostomy and closure of the rectal stump) and resection with colonic washout and anastomosis (± defunctioning loop ileostomy). Primary anastomosis should be used selectively but is appealing in a young fit patient without...
gloss contamination or overwhelming sepsis. However, this is a relatively rare scenario and the majority of emergency operations for perforated diverticular disease are Hartmann’s procedures (Figure 69.38). There is good evidence that simple defunctioning with a proximal stoma is associated with higher mortality than a resection. There may be an emerging role for emergency laparoscopy in diverticular disease with washout if there is no faecal contamination (i.e. Hinchey grade III or less), avoiding sigmoid resection. At present, this remains in the domain of the experienced laparoscopic surgeon.

Indications for surgery in an elective setting are controversial. There are undoubtedly a small number of patients with recurrent attacks who should be offered an elective sigmoid colectomy (with anastomosis). This could be performed laparoscopically in experienced hands with a likely but not clearly proven swifter recovery, as well as improved cosmesis. Cohort series studies suggest that of younger patients (under 50 years old) admitted with diverticulitis, 25 per cent will get a further episode. This is used as an argument for offering elective resection, but equally suggests 75 per cent will not have another severe attack. Many surgeons would discuss the pros and cons of elective surgery after two emergency admissions, although general health must be carefully considered. There has been an increasing tendency, in recent years, to treat even patients with recurrent attacks of diverticulitis conservatively in the absence of complications.

Diverticular fistulae can only be cured by resection of the affected bowel, although a defunctioning stoma can ameliorate symptoms. In the most common scenario of a colovesical fistula, the sigmoid can often be pinched off the bladder and the sigmoid resected. If an anastomosis is performed, it is wise to place an omental pedicle to prevent recurrent fistulation. There will be occasions when a bladder resection is required and it is ideal to involve a urologist or general surgeon experienced in bladder surgery.

A recent study shows that diverticulitis should be distinguished from angiodysplasia. It usually responds to conservative management and only occasionally requires resection. Where available angiography is helpful to localise bleeding points. On-table lavage and colonoscopy may be necessary to localise the bleeding site. If the source cannot be located, then subtotal colectomy and ileostomy is the safest option.

**VASCULAR ANOMALIES OF THE INTESTINE**

**Mesenteric ischaemia**

Mesenteric vascular disease may be classified as acute intestinal ischaemia – with or without occlusion – venous, chronic arterial, central or peripheral. The superior mesenteric vessels are the visceral vessels most likely to be affected by embolisation or thrombosis, with the former being most common. Occlusion at the origin of the superior mesenteric artery (SMA) is almost invariably the result of thrombosis, whereas emboli lodge at the origin of the middle colic artery. Inferior mesenteric involvement is usually clinically silent because of a better collateral circulation.

Possible sources for the embolisation of the SMA include a left atrium associated with fibrillation, a mural myocardial infarction, an atheromatous plaque from an aortic aneurysm and a mitral valve vegetation associated with endocarditis.

Primary thrombosis is associated with atherosclerosis and thromboangiitis obliterans. Primary thrombosis of the superior mesenteric veins may occur in association with factor V Leiden, portal hypertension, portal pyaemia and sickle cell disease and in women taking the contraceptive pill.

Irrespective of whether the occlusion is arterial or venous, haemorrhagic infarction occurs. The mucosa is the only layer of the intestinal wall to have little resistance to ischaemic injury. The intestine and its mesentery become swollen and oedematous. Blood-stained fluid exudes into the peritoneal cavity and bowel lumen. If the main trunk of the SMA is involved, the infarction covers an area from just distal to the duodenojejunal flexure to the splenic flexure. Usually, a branch of the main trunk is implicated and the area of infarction is less.

**Clinical features**

The most important clue to an early diagnosis of acute mesenteric ischaemia is the sudden onset of severe abdominal pain in a patient with atrial fibrillation or atherosclerosis. The pain is typically central and out of all proportion to physical findings. Persistent vomiting and defaecation occur early, with the subsequent passage of altered blood. Hypovolaemic shock rapidly ensues. Abdominal tenderness may be mild initially with rigidity being a late feature.
Investigation will usually reveal a profound neutrophil leucocytosis with an absence of gas in the thickened small intestine on abdominal radiographs. The presence of gas bubbles in the mesenteric veins is rare but pathognomonic.

Treatment needs to be tailored to the individual. In conjunction with full resuscitation, embolectomy via the ileocolic artery or revascularisation of the SMA may be considered in early embolic cases. The majority of cases, however, are diagnosed late. In the young, all affected bowel should be resected, whereas in the elderly or infirm the situation may be deemed incurable. Anticoagulation should be implemented early in the postoperative period.

After extensive enterectomy, it is usual for patients to require intravenous alimentation. The young, however, may sometimes develop sufficient intestinal digestive and absorptive function to lead relatively normal lives. In selected cases, consideration may be given to small bowel transplantation.

Infarction of the large intestine alone is relatively rare. Involvement of the middle colic artery territory should be treated by transverse colectomy and exteriorisation of both ends, with an extended right haemicolectomy in selected cases.

Ischaemic colitis describes the structural changes that occur in the colon as a result of the deprivation of blood. They are most common in the splenic flexure, whose blood supply is particularly tenuous. They have been classified by Marston into gangrenous, transient and stricturing forms; only stricturing forms cause obstruction and only a few such patients require resection.

**Angiodysplasia**

Angiodysplasia is a vascular malformation that is a cause of haemorrhage from the colon, typically in patients over 60 years. The lesions are also called angiomas, haemangiomas and arteriovenous malformations. Angiodysplasias occur particularly in the ascending colon and caecum of elderly patients. The malformations consist of dilated tortuous submucosal veins and in severe cases the mucosa is replaced by massive dilated deformed vessels.

**Clinical features**

In the majority, the symptoms are subtle and patients can present with anaemia. About 10–15 per cent of patients have brisk bleeds, which may present as melaena or significant rectal bleeding. It is likely that in many patients in whom rectal bleeding has been attributed to diverticular disease, bleeding was in fact from angiodysplasia. There is an association with aortic stenosis (Heyde’s syndrome).

**Investigation**

If the bleeding is not too brisk, colonoscopy may show the characteristic lesion in the right colon. The lesions are only a few millimetres in size and appear as reddish, raised areas at endoscopy. Capsule endoscopy is a relatively new technology that may detect small bowel lesions. Selective superior and inferior mesenteric angiography shows the site and extent of the lesion by a ‘blush’ of contrast provided bleeding is above 1 mL/min. If this fails, a technetium-99m (99mTc)-labelled red cell scan may confirm and localise the source of bleeding.

**Treatment**

The first principle is to stabilise the patient. Following this, the bleeding needs to be localised. Colonoscopy may allow cauterisation to be carried out. In severe uncontrolled bleeding, surgery becomes necessary. On-table colonoscopy is carried out to confirm the site of bleeding. Angiodysplastic lesions are sometimes demonstrated by transillumination through the caecum (Figure 69.39). If it is still not clear exactly which segment of the colon is involved, then a subtotal colectomy may be necessary.

**Ischaemic colitis**

Ischaemia of the colon typically results from thrombosis or embolism. Sudden embolic events present with severe pain out of proportion to the degree of peritonism, bloody diarrhoea, severe haemodynamic instability and acidosis. Resuscitation and laparotomy are required with resection of gangrenous bowel and exteriorisation of the bowel. Mortality is extremely high. If the disease process is thrombotic in the context of global atherosclerosis, the presentation tends to be less dramatic with intermittent abdominal pain and rectal bleeding. Abdominal radiographs may show ‘thumbprinting’ and endoscopy may demonstrate haemorrhagic oedema. The left colon and, in particular, the splenic flexure are usually the worst affected. Angioplasty and bypass procedures can be performed in these circumstances, but are rarely required as symptoms usually settle spontaneously. In some cases, ulceration at the splenic flexure associated with ischaemic colitis may heal with stricturing and present with subsequent large bowel obstruction.

**STOMAS**

A colostomy (or ileostomy) stoma is an artificial opening made in the colon (or small intestine) to divert faeces and flatus outside the abdomen where they can be collected in an external appliance. Depending on the purpose for which the diversion has been necessary, a stoma may be temporary or permanent (Summary box 69.18).
Loop colostomy

A transverse loop colostomy has in the past been used to defunction an anastomosis after an anterior resection. It is now less commonly employed, as it is difficult to manage and potentially disrupts the marginal arterial supply to the anastomosis. Loop transverse colostomies are also particularly prone to prolapse. A loop ileostomy is now more commonly used.

A loop left iliac fossa colostomy is still sometimes used to prevent faecal peritonitis developing following traumatic injury to the rectum, to facilitate the operative treatment of a high fistula in ano, for incontinence and to defunction a near obstructing rectal cancer prior to long course chemoradiotherapy (see Chapter 72).

A temporary loop colostomy is made by bringing a mobilised loop of colon to the surface, where it is held in place by a plastic bridge passed through a mesenteric window created just at the junction with the colon. Once the abdomen has been closed, the colostomy is opened, and the edges of the colonic incision are sutured to the adjacent skin margin (Figure 69.40). When firm adhesion of the colostomy to the abdominal wall has taken place, the bridge can be removed.

Following healing of the distal lesion for which the temporary stoma was constructed, the colostomy can be closed. It is usual to perform a contrast examination (proctogram) to check that there is no distal obstruction or continuing problem at the site of previous surgery. Colostomy closure is most easily and safely accomplished if the stoma is mature, typically after the colostomy has been established for two months. Closure is usually possible with a circumstomal incision, which avoids a full laparotomy, but it is important for patient and surgeon to consider the risks of closure carefully as it does involve a bowel anastomosis. In some cases, a full laparotomy may be required for safe closure of the stoma.

End colostomy

This is formed after an abdominoperineal excision of the rectum or as part of a Hartmann’s procedure bringing the divided colon through a left iliac fossa trephine in rectus abdominis and skin. The colonic margin is then sutured to the adjoining skin.

The point at which the colon is brought to the surface must be carefully selected to allow a colostomy bag to be applied without impinging on the bony prominence of the anterosuperior iliac spine. The best site is usually through the lateral edge of the rectus sheath, above and medial to the bony prominence (Figure 69.41).

Closure of the lateral space between the intraperitoneal segment of the sigmoid colon and the peritoneum of the pelvic wall, to prevent internal herniation or strangulation of loops of small bowel through the deficiency, has been practised, but there is no good evidence that it is effective.

Loop ileostomy

A loop ileostomy is often used for defunctioning a low rectal anastomosis or an ileal pouch. A knuckle of ileum is pulled out through a skin trephine in the right iliac fossa. An incision is made in the distal part of the knuckle, and this is then pulled

Figure 69.40 Temporary (loop) colostomy opened over a rod, and immediate suture of the colon wall to surrounding skin (alternatively, a skin bridge is used).

Figure 69.41 A colostomy in the left iliac fossa.
over the top of the more proximal part to create a spout on the proximal side of the loop with a flush distal side still in continuity. This allows near perfect defunction, but also the possibility of restoration of continuity by taking down the spout and reanastomosing the partially divided ileum.

The advantages of a loop ileostomy over a loop colostomy are the ease with which the bowel can be brought to the surface and the absence of odour. Care is needed when the ileostomy is closed, so that suture line obstruction does not occur. Closure of a loop ileostomy can be a technically challenging procedure, particularly if there are dense adhesions resulting from previous surgery.

### End ileostomy

An end ileostomy is formed after a subtotal colectomy without anastomosis when it may later be reversed or may be permanent after a panproctocolectomy. The ileum is normally brought through the rectus abdominis muscle. Careful attention to the terminal ileal mesentery should be taken to ensure that it is not too bulky. The use of a spout was originally described by Bryan Brooke; this should project some 4 cm from the skin surface (Figure 69.42). A disposable appliance is placed over the ileostomy so that it is a snug fit at skin level.

There may be an ‘ileostomy flux’ while the ileum adapts to the loss of the colon. While ileostomy output can amount to 4 or 5 litres per day, losses of 1–2 litres are more common. A consistent ileostomy output in excess of 1.5 litres is usually associated with dehydration and sodium depletion in the absence of intravenous therapy. The stools thicken in a few weeks and are semisolid in a few months. The help, skill and advice of the stoma care nurse specialist are essential. Modern appliances have transformed stoma care, and skin problems are unusual (Figure 69.43). Complications of an ileostomy include prolapse, retraction, stenosis, bleeding, fistula and parastomal hernia.

### Stoma bags and appliances

Stoma output is collected in disposable adhesive bags. Ileostomy appliances tend to be drainable bags, which are left in place for 48 hours, while colostomy appliances are simply changed two or three times each day. A wide range of such bags is currently available. Many now incorporate an adhesive backing, which can be left in place for several days. In most hospitals, a stoma care service is available to offer advice to patients, to acquaint them with the latest appliances and to provide the appropriate psychological and practical help.

### Caecostomy

In unstable patients with advanced obstruction, a caecostomy may be useful. In late cases of obstruction, the caecum may become so distended and ischaemic that rupture of the caecal wall may be anticipated. This can occur spontaneously, giving rise to faecal peritonitis, or at operation, when an incision in the abdominal wall reduces its supportive role and allows the caecum to expand. In such a situation, it should be decompressed by suction as soon as the abdomen is opened. In thin patients, it may then be possible to carry out direct suture of the incised or perforated caecal wall to the abdominal skin of the right iliac fossa, although resection of this area is really the best treatment preferable. Following on-table lavage, via the appendix stump, the irrigating catheter can be left in place as a tube caecostomy.

### Complications of stomas

Stoma complications are underestimated and common (Summary box 69.19). On occasion, these complications require surgical revision. Sometimes, this can be achieved with an incision immediately around the stoma, but on occasion reopening the abdomen and freeing up the stoma may be necessary. Repair of parastomal hernias is particularly technically challenging and the recurrence rate is high. Simple suture of the parastomal hernia is associated with an almost 100 per cent risk of recurrence and transfer to the opposite side of the abdomen, or insertion of a piece of prosthetic material within the abdominal wall around the stoma may be necessary.

### Summary box 69.19

**Stoma complications**
- Skin irritation
- Prolapse
- Retraction
- Ischaemia
- Stenosis
- Parastomal hernia
- Bleeding
- Fistulation
CONDITIONS CAUSING MALABSORPTION

Coeliac disease
Coeliac disease is the most common cause of malabsorption in the UK with a stated prevalence of 1:1800, although this may be an underestimate. It is characterised by a hypertrophic small bowel mucosa with atrophic villi and deep crypts. It is thought that loss of surface area and brush border enzymes results in malabsorption.

Coeliac disease is caused by gluten, a cereal protein although the exact mechanism remains unclear. There is a genetic component as the disease is more common in first-degree relatives and has an association with HLA B8. In children, coeliac disease presents with steatorrhoea and growth retardation. In adults, it results in diarrhoea, weight loss and anaemia.

The diagnosis is made after an endoscopic duodenal biopsy allows pathological examination of mucosa. The antiendomysial antibody tests have a very high sensitivity and specificity for coeliac disease, but many gastroenterologists would still want a biopsy to be entirely certain of the diagnosis.

Patients with coeliac disease have an increased risk of small bowel lymphoma and adenocarcinoma. Extraintestinal complications are dermatitis herpetiformis and neurological problems.

The key treatment for coeliac disease is withdrawal of gluten from the diet by avoiding wheat, rye and barley. Surgery is reserved for malignancy.

Bacterial overgrowth
The small intestine can become colonised with bacteria normally confined to the colon if there is stasis resulting in delayed bacterial clearance (blind loop syndrome, Figure 69.44). If this occurs in the upper intestine, the defect is chiefly of fat absorption; if in the lower intestine, there is vitamin B12 deficiency. There is relatively little effect on carbohydrate or protein metabolism.

Essentially, the stasis produces an abnormal bacterial flora, which prevents proper breakdown of fat and mops up the vitamins that are present. Sometimes, the only manifestation is anaemia, resulting from vitamin B12 deficiency but, if steatorrhoea occurs, other serious malabsorption features may follow including glossitis, osteomalacia, paraesthesia and peripheral neuropathy.

Improvement normally follows after intermittent therapy with oral antibiotics; metronidazole, ciprofloxacin and tetracycline are commonly used. Definitive treatment is surgical to remove the ‘blind loop’, but this is not always feasible.

FUNCTIONAL ABNORMALITIES

Constipation
There is no single definition of constipation; however, a bowel frequency of less than one every 3 days is commonly considered to be abnormal. Although constipation is often regarded as a trivial symptom, some patients are greatly disabled by abdominal pain, distension, reliance on laxatives and difficulty with defaecation. It is an extremely prevalent complaint in western society. Some reports have put the annual prescription sales for laxatives in the UK at around £50 million. These are usually otherwise healthy individuals who seek help for constipation, but eat a normal diet and have a normal colon on endoscopy and barium enema. Constipation can be divided into:

- megacolon:
  - Hirschsprung’s disease;
  - non-Hirschsprung’s megacolon and megarectum;
- non-megacolon:
  - secondary to drugs or illness;
  - primary colonic problem.

Hirschsprung’s disease
The nature and treatment of Hirschsprung’s disease is discussed with other congenital disorders in Chapter 70.

Idiopathic megacolon and megarectum
This is a rare condition and the cause is not known, although in some it may result from poor toilet training during infancy and in others from a congenital abnormality of the intestinal myenteric plexus. In South America, Chagas disease is a common cause of megacolon resulting from infection with *Trypanosoma cruzi*. Volvulus and perforation can occur and treatment may require surgical resection.

Harald Hirschsprung, 1830–1916, physician, The Queen Louise Hospital for Children, Copenhagen, Denmark described congenital megacolon in 1887.

Figure 69.44 Common types of blind loop. (a) Self-filling: deficiency occurs; (b) self-emptying: no deficiency occurs; (c) long afferent loop stasis in Pólya gastrectomy; (d) jejunal diverticula; (e) intestinal stricture causing stasis; (f) ‘stenosis–anastomosis loop’ syndrome.
Clinical features
Idiopathic megacolon usually presents with severe constipation before the age of 20. Patients with idiopathic megarectum often present with faecal incontinence due to rectal faecal loading that requires manual evacuation. Patients with megacolon are more likely to present with abdominal distension and pain. On clinical examination, there may be a hard faecal mass arising out of the pelvis and, on rectal examination, there is a large faecal mass in the lumen. The anus is usually patulous, perianal soiling is common, and sigmoidoscopy is usually impossible but may show melanosis coli if the patient has been taking laxatives over many years.

Investigation
Anorectal physiology tests demonstrate delayed sensation and raised maximum tolerated volume. Full-thickness rectal biopsy shows normal ganglion cells, a finding that definitively distinguishes this condition from Hirschsprung’s disease. Radiology studies will show gross faecal loading of the enlarged rectum and colon and an enlarged rectum (Figure 69.45).

Medical treatment
This is directed at emptying the rectum and keeping it empty with enemas, washouts and occasionally, manual evacuation under anaesthesia. Thereafter, the patient is encouraged to develop a regular daily bowel habit, with the use of osmotic laxatives to help the passage of semiformed stool. Rectal evacuation with suppositories and biofeedback therapy may be useful in resistant cases.

Surgical treatment
Surgical treatment is sometimes necessary if medical therapy fails. Options that are available include:
- resection of the dilated rectum and colon (Figure 69.46) back to normal-diameter colon followed by reconstruction with a coloanal anastomosis;
- colectomy with the formation of an ileorectal anastomosis if the rectum is spared;
- restorative proctocolectomy;
- vertical reduction rectoplasty, which is a procedure designed to reduce the volume of the rectum by at least 50 per cent;
- stoma formation, which may be used either as a salvage operation for failure of previous surgery or as a primary intervention.

Non-megacolon constipation
Drugs and a range of illnesses can result in constipation (see Summary boxes 69.20 and 69.21). Altering medication or addition of laxatives can be helpful for drug-related constipation, correction of underlying illness is clearly ideal where possible for the conditions in Summary box 69.21.

Summary box 69.20
Drugs that can cause constipation
- Benzodiazepines
- Carbamazepine
- Chlorpromazine
- Cholestyramine
- Iron
- Opiates, particularly codeine and morphine
- Tricyclic antidepressants
- Statins
There remain a group of patients with significant constipation who do not have any structural, pharmacological or other pathology to explain their symptoms. Some will have obstructed defaecation and this is discussed in Chapter 72. Others will have slow colonic transit, a disorder usually seen in women, which may have been present since childhood or may suddenly follow abdominal or pelvic surgery. Marker studies will reveal delayed transit, and the patient may or may not be able to empty the rectum normally.

**Investigation**

Whole-gut transit time can be measured by asking the patient to stop all laxatives and take a capsule containing radio-opaque markers (Figure 69.47). Retention of more than 80 per cent of the shapes, 120 hours after ingestion, is abnormal.

Defaecating proctography will demonstrate intussusception and rectocele if they are causing obstructed defaecation (Chapter 72).

**Treatment of slow colonic transit**

- **Dietary fibre.** This is the first-line treatment for people with mild constipation. Constipation only resolves after several weeks of therapy and usually needs to be continued in the long term.
- **Laxatives.** It is important that patients do not fall into a cycle of laxative abuse. A number of types are available which include bulk, osmotic and stimulant agents.
- **Biofeedback.** This involves conditioning and coordination of the abdominal and pelvic compartments. It has been shown to be effective in those with a rectal evacuation problem and has also been used in slow transit with some benefit.
- **Surgery.** This is a difficult condition to treat medically; dietary measures are usually unsuccessful, and surgical treatment is justified after careful studies and when medical treatment has been exhausted. Total colectomy and ileorectal anastomosis is the preferred procedure, but the results are unpredictable. Studies show complications of intermittent small bowel obstruction (60 per cent), further surgery (30 per cent), constipation (25 per cent), diarrhoea (25 per cent) and incontinence (10 per cent). This may be explained in part by the argument that colectomy does not address the functional problem of the remaining bowel. Patients need to be carefully selected for surgery and psychological evaluation may be of benefit. Other types of surgery performed for slow transit constipation include stoma creation and segmental resection, but results are variable.

**Irritable bowel syndrome**

The term ‘irritable bowel syndrome’ (IBS) covers a range of symptom patterns that have a functional basis, i.e. no anatomical abnormality has been found. The clinical features are therefore variable but abdominal pain, bloating, irregularity of bowel habit and passage of mucous are common. Colonic investigations are typically performed to rule out organic disease (colonoscopy, barium enema or CT virtual colonoscopy).

Treatment is difficult by its nature. Many patients benefit from reassurance that there is no sinister pathology and symptomatic treatment; fibre or Fybogel for constipation, loperamide for diarrhoea. Reduction of caffeine intake and nicotine intake may be helpful. Antispasmodic agents are commonly prescribed, but the evidence base for this is poor. There is evidence of benefit for low-dose tricyclic antidepressants, but some patients are reluctant to use them because of a perceived stigma. Psychological treatments have been shown to be beneficial including hypnotherapy and cognitive behavioural therapy.

**ENTEROCUTANEOUS FISTULA**

An abnormal connection between small bowel and skin can occur in fistulating Crohn’s disease or as a result of radiotherapy or abdominal trauma, but most commonly follows a surgical...
complication – either a leak from an anastomosis or an inadvertent enterotomy during dissection. This can be very challenging to manage in patients with a high-output fistula (>500 mL/day). Low-output fistulae (<500 mL/day) can be expected to heal spontaneously, provided there is no distal obstruction. Reasons for failure of spontaneous healing also include:

- epithelial continuity between the gut and the skin;
- the presence of active disease where, for example, there is Crohn’s disease or carcinoma at the site of the anastomosis or in the fistula track;
- an associated complex abscess.

The management of high output fistulae is based on well-established principles (‘SNAP’, see Summary box 69.22), as an early return to theatre to try and fix the problem in a septic, malnourished patient is doomed to failure.

**Summary box 69.22**

**Principles of management of enterocutaneous fistulae (SNAP)**

- S, elimination of Sepsis and skin protection
- N, Nutrition – a period of parenteral nutrition may well be required
- A, Anatomical assessment
- P, definitive Planned surgery

Infected collections are best identified at CT (Figure 69.48) and can be drained percutaneously. Skin protection is important, as small bowel effluent is caustic. Nutritional support must include fluid and electrolytes, which can be lost in high quantities from a proximal fistula as well as carbohydrates, protein, fat and vitamins. Judgements have to be made between enteral and parenteral feeding – enteral feeding has advantages but if the fistula is proximal or high output, total parenteral nutrition (TPN) will be required. Defining anatomy is best done after careful discussion with the radiologist – a sequence of contrast studies (follow-through, fistulogram and enema) may well be required to define bowel length and plan a surgical strategy. The surgery can on occasion be extremely technically demanding, and an anastomosis should not be fashioned in the presence of continuing intra-abdominal sepsis or when the patient is hypoproteinanaemic.

**FURTHER READING**

Intestinal obstruction may be classified into two types:

- **Dynamic**, in which peristalsis is working against a mechanical obstruction. It may occur in an acute or a chronic form (Figure 70.1 and Summary box 70.1).
- **Adynamic**, in which there is no mechanical obstruction; peristalsis is absent or inadequate (e.g. paralytic ileus or pseudo-obstruction).

**Summary box 70.1**

**Causes of intestinal obstruction**

**Dynamic**
- Intraluminal
  - Faecal impaction
  - Foreign bodies
  - Bezoars
  - Gallstones
- Intramural
  - Stricture
  - Malignancy
  - Intussusception
  - Volvulus
- Extramural
  - Bands/adhesions
  - Hernia

**Adynamic**
- Paralytic ileus
- Pseudo-obstruction

**PATHOPHYSIOLOGY**

Irrespective of aetiology or acuteness of onset, in dynamic (mechanical) obstruction the bowel proximal to the obstruction dilates and the bowel below the obstruction exhibits normal peristalsis and absorption until it becomes empty and collapses. Initially, proximal peristalsis is increased in an attempt to overcome the obstruction. If the obstruction is not relieved, the bowel continues to dilate, ultimately there is a reduction in peristaltic strength, resulting in flaccidity and paralysis.

The distension proximal to an obstruction is caused by two factors:

- **Gas**: there is a significant overgrowth of both aerobic and anaerobic organisms, resulting in considerable gas production. Following the reabsorption of oxygen and carbon dioxide, the majority is made up of nitrogen (90 per cent) and hydrogen sulphide.
- **Fluid**: this is made up of the various digestive juices (saliva 500 mL, bile 500 mL, pancreatic secretions 300 mL, gastric secretions 1 litre – all per 24 hours). This accumulates in the gut lumen as absorption by the obstructed gut is retarded. Dehydration and electrolyte loss are therefore due to:
  - reduced oral intake;
PART 11
ABDOMINAL

INTESTINAL OBSTRUCTION

- defective intestinal absorption;
- losses as a result of vomiting;
- sequestration in the bowel lumen;
- transudation of fluid into the peritoneal cavity.

STRANGULATION

It is important to appreciate that the consequences of intestinal obstruction are not immediately life-threatening unless there is superimposed strangulation. When strangulation occurs, the blood supply is compromised and the bowel becomes ischaemic (Summary box 70.2).

Summary box 70.2

Causes of strangulation

- Direct pressure on the bowel wall
  - Hernial orifices
  - Adhesions/bands
- Interrupted mesenteric blood flow
  - Volvulus
  - Intussusception
- Increased intraluminal pressure
- Closed-loop obstruction

Ischaemia from direct pressure on the bowel wall from a constricting band, such as a hernial orifice, is easy to understand.

Distention of the obstructed segment of bowel results in high pressure within the bowel wall. This can happen when only part of the bowel wall is obstructed as seen in Richter’s hernias. Venous return is compromised before the arterial supply. The resultant increase in capillary pressure leads to impaired local perfusion and once the arterial supply is impaired, haemorrhagic infarction occurs. As the viability of the bowel is compromised, translocation and systemic exposure to anaerobic organisms and endotoxin occurs.

The morbidity and mortality associated with strangulation are largely dependent on the duration of the ischaemia and its extent. Elderly patients and those with comorbidities are more vulnerable to its effects. Although in strangulated external hernias the segment involved is often short, any length of ischaemic bowel can cause significant systemic effects secondary to sepsis and obstruction proximal to the obstruction can result in significant dehydration. When bowel involvement is extensive circulatory failure is common.

Closed-loop obstruction

This occurs when the bowel is obstructed at both the proximal and distal points (Figure 70.2). The distention is principally confined to the closed loop, distention proximal to the obstructed segment is not typically marked.

A classic form of closed-loop obstruction is seen in the presence of a malignant stricture of the colon with a competent ileocaecal valve (present in up to one-third of individuals). This can occur with lesions as far distally as the rectum. The inability of the distended colon to decompress itself into the small bowel results in an increase in luminal pressure, which is greatest at the caecum, with subsequent impairment of blood flow in the wall. Unrelieved, this results in necrosis and perforation (Figure 70.3).

Figure 70.2 Distension. Closed-loop obstruction with no proximal (A) or distal (C) distension and impending strangulation [B].

Figure 70.3 Carcinomatous stricture (X) of the hepatic flexure: closed-loop obstruction.

SPECIAL TYPES OF MECHANICAL INTESTINAL OBSTRUCTION

Internal hernia

Internal herniation occurs when a portion of the small intestine becomes entrapped in one of the retroperitoneal fossae or in a congenital mesenteric defect.

The following are potential sites of internal herniation (all are rare):

- the foramen of Winslow;
- a defect in the mesentery;
- a defect in the transverse mesocolon;
- defects in the broad ligament;
- congenital or acquired diaphragmatic hernia;
- duodenal retroperitoneal fossae – left paraduodenal and right duodenojejunal;

Jacob Benignus Winslow, 1669–1760, Professor of Anatomy, Physic and Surgery, Paris, France.
Special types of mechanical intestinal obstruction

Trychobezoars and phytobezoars

These are firm masses of undigested hair ball and fruit/vegetable fibre, respectively. The former is due to persistent hair chewing or sucking, and may be associated with an underlying psychiatric abnormality. Predisposition to phytobezoars results from a high fibre intake, inadequate chewing, previous gastric surgery, hypochlorhydria and loss of the gastric pump mechanism. When possible, the lesion may be kneaded into the caecum, otherwise open removal is required. A peroperative diagnosis is difficult even with high resolution computed tomography (CT) scanning.

Stercoliths

These are usually found in the small bowel in association with a jejunal diverticulum or ileal stricture. Presentation and management are identical to that of gallstones.

Worms

Ascaris lumbricoides may cause low small bowel obstruction, particularly in children, the institutionalised and those near the tropics (Figure 70.4). An attack may follow the initiation of antihelminthic therapy. Debility is frequently out of proportion to that produced by the obstruction. If worms are not seen in the stool or vomitus, the diagnosis may be indicated by eosinophilia or the sight of worms within gas-filled small bowel loops on a plain radiograph (Naik). At laparotomy, it may be possible to knead the tangled mass into the caecum; if not it should be removed. Occasionally, worms may cause a perforation and peritonitis, especially if the enteric wall is weakened by such conditions as amebiasis.

Obstruction by adhesions and bands

Adhesions

In Western countries where abdominal operations are common, adhesions and bands are the most common cause of intestinal obstruction. The lifetime risk of requiring an admission to hospital for adhesional small bowel obstruction subsequent to abdominal surgery is around 4 per cent and the risk of requiring a laparotomy around 2 per cent. Adhesions start to form within

Food

Bolus obstruction may occur after partial or total gastrectomy when unchewed articles can pass directly into the small bowel. Fruit and vegetables are particularly liable to cause obstruction. The management is similar to that for gallstone, with intraluminal crushing usually being successful.

Figure 70.4 Obstruction of the small intestine due to Ascaris lumbricoides (courtesy of Asal Y Izzidien, Nenavah, Iraq).

Vinod C Naik, a doctor from Navsari, India.
hours of abdominal surgery. In the early postoperative period, the onset of such a mechanical obstruction may be difficult to differentiate from paralytic ileus.

The causes of intraperitoneal adhesions are shown in Table 70.1. Any source of peritoneal irritation results in local fibrin production, which produces adhesions between apposed surfaces. Early fibrinous adhesions may disappear when the cause is removed or they may become vascularised and be replaced by mature fibrous tissue.

There are several factors that may limit adhesion formation (Summary box 70.3).

### Summary box 70.3

**Prevention of adhesions**

Factors that may limit adhesion formation include:

- Good surgical technique
- Washing of the peritoneal cavity with saline to remove clots
- Minimising contact with gauze
- Covering anastomosis and raw peritoneal surfaces

Numerous substances have been instilled in the peritoneal cavity to prevent adhesion formation, including hyaluronidase, hydrocortisone, silicone, dextran, polyvinylpropylene (PVP), chondroitin and streptomyacin, anticoagulants, antihistamines, non-steroidal anti-inflammatory drugs and streptokinase. Currently, no single agent or combination of agents has been convincingly shown to be effective. It is hoped that with the more widespread use of laparoscopic surgery, the incidence of intra-abdominal adhesions will reduce.

Adhesions may be classified into various types by virtue of whether they are early (fibrinous) or late (fibrous) or by underlying aetiology. From a practical perspective, there are only two types – ‘easy’ flimsy ones and ‘difficult’ dense ones.

Postoperative adhesions giving rise to intestinal obstruction usually involve the lower small bowel and almost never involve the large bowel.

### Bands

Usually only one band is culpable. This may be:

- congenital, e.g. obliterated vitellointestinal duct;
- a string band following previous bacterial peritonitis;
- a portion of greater omentum, usually adherent to the parietes.

**Acute intussusception**

This occurs when one portion of the gut invaginates into an immediately adjacent segment; almost invariably, it is the proximal into the distal.

The condition is encountered most commonly in children, with a peak incidence between five and ten months of age. About 90 per cent of cases are idiopathic, but an associated upper respiratory tract infection or gastroenteritis may precede the condition. It is believed that hyperplasia of Peyer’s patches in the terminal ileum may be the initiating event. Weaning, loss of passively acquired maternal immunity and common viral pathogens have all been implicated in the pathogenesis of intussusception in infancy.

Children with intussusception associated with a pathological lead point such as Meckel’s diverticulum, polyp, duplication, Henoch–Schönlein purpura or appendix are usually older than those with idiopathic disease. After the age of two years, a pathological lead point is found in at least one-third of affected children. Adult cases are invariably associated with a lead point, which is usually a polyp (e.g. Peutz–Jeghers syndrome), a submucosal lipoma or other tumour.

### Pathology

An intussusception is composed of three parts (Figure 70.5):

- the entering or inner tube (intussusceptum);
- the returning or middle tube;
- the sheath or outer tube (intussuscipiens).

The part that advances is the apex, the mass is the intussusception and the neck is the junction of the entering layer with the mass.

Intussusception may be anatomically defined according to the site and extent of invagination (Table 70.2). In most children, the intussusception is ileocolic (see Chapter 8, Figure 6.16). In adults, colocolic intussusception is more common (Summary box 70.4). The degree of ischaemia is dependent on the tightness of the invagination, which is usually greatest as it passes through the ileocaecal valve. On CT scanning, the target sign may be evident and if present is pathognomonic. It is worth noting that rarely, intussusception has been noted on CT scanning in asymptomatic adults.

Summary box 70.4

Intussusception

- Most common in children
- Adult cases are secondary to intestinal pathology, e.g. polyp, Meckel’s diverticulum
- Ileocolic is the most common variety
- Can lead to an ischaemic segment
- Radiological reduction is indicated in most paediatric cases
- Adults require surgery

Volvulus neonatorum

This occurs secondary to intestinal malrotation (see Chapter 8) and is potentially catastrophic.

Sigmoid volvulus

This is uncommon in Europe and the United States, but more common in Eastern Europe and Africa. Indeed, it is the most common cause of large bowel obstruction in the indigenous Black African population. Rotation nearly always occurs in the anticlockwise direction. The predisposing causes are summarised in Figure 70.6. Other predisposing factors include a high residue diet and constipation. In Western populations, the condition is seen most often in elderly patients with chronic constipation; comorbidities are common and chronic psychotropic drug use is associated with this condition. Younger patients present earlier and the prognosis is inversely related to the duration of symptoms. Presentation can be classified as:

- **Fulminant**: sudden onset, severe pain, early vomiting, rapidly deteriorating clinical course;
- **Indolent**: insidious onset, slow progressive course, less pain, late vomiting.

Compound volvulus

This is a rare condition also known as ileosigmoid knotting. The long pelvic mesocolon allows the ileum to twist around the sigmoid colon, resulting in gangrene of either or both segments of bowel. The patient presents with acute intestinal obstruction, but distension is comparatively mild. Plain radiography reveals distended ileal loops in a distended sigmoid colon. At operation, decompression, resection and anastomosis are required.

Summary box 70.5

Volvulus

- May involve the small intestine, caecum or sigmoid colon; neonatal midgut volvulus secondary to midgut malrotation is life-threatening
- The most common spontaneous type in adults is sigmoid
- Sigmoid volvulus can be relieved by decompression per anum
- Surgery is required to prevent or relieve ischaemia

Figure 70.6 Causes predisposing to volvulus of the sigmoid colon. Idiopathic megacolon usually precedes the volvulus in African people.
The underlying mechanisms are shown in Summary box 70.2. The common causes of intestinal obstruction in Western countries and their relative frequencies are shown in Figure 70.1. The underlying mechanisms are shown in Summary box 70.2.

**Summary box 70.6**

**Features of obstruction**
- **In high small bowel obstruction**, vomiting occurs early, is profuse and causes rapid dehydration. Distension is minimal with little evidence of dilated small bowel loops on abdominal radiography.
- **In low small bowel obstruction**, pain is predominant with central distension. Vomiting is delayed. Multiple dilated small bowel loops are seen on radiography.
- **In large bowel obstruction**, distension and pronounced. Pain is less severe and vomiting and dehydration are later features. The colon proximal to the obstruction is distended on abdominal radiography. The small bowel will be dilated if the ileocaecal valve is incompetent.

The nature of the presentation will also be influenced by whether the obstruction is:
- complete
- incomplete.

A complete small bowel obstruction has all the cardinal features (Summary box 70.7). In cases of complete large bowel obstruction, there is often a surprising lack of preceding symptoms. Both small and large bowel obstruction can present with more chronic symptoms in which the symptoms are intermittent or the obstruction is incomplete. Incomplete obstruction is also referred to as partial or subacute.

**Summary box 70.7**

**Cardinal clinical features of acute obstruction**
- Abdominal pain
- Distension
- Vomiting
- Absolute constipation

Presentation will be further influenced by whether the obstruction is:
- simple – in which the blood supply is intact;
- strangulating/strangulated – in which there is interference to blood flow.

The clinical features vary according to:
- the location of the obstruction;
- the duration of the obstruction;
- the underlying pathology;
- the presence or absence of intestinal ischaemia.

Late manifestations of intestinal obstruction that may be encountered include dehydration, oliguria, hypovolaemic shock, pyrexia, septicaemia, respiratory embarrassment and peritonism. In all cases of suspected intestinal obstruction, the hernial orifices must be examined.

**Pain**

Pain is the first symptom encountered; it occurs suddenly and is usually severe. It is colicky in nature and usually centred on the umbilicus (small bowel) or lower abdomen (large bowel). The pain coincides with increased peristaltic activity. With increasing distension, the colicky pain is replaced by a mild and more constant diffuse pain. If there is no ischaemia and the obstruction persists over several days, pain reduces and can disappear.

The development of severe pain is suggestive of the presence of strangulation, especially if that severe pain is continuous. Beware the patient whose pain is not controlled with intravenous opiates. Colicky pain may not be a significant feature in postoperative simple mechanical obstruction and pain does not usually occur in paralytic ileus.

**Vomiting**

The more distal the obstruction, the longer the interval between the onset of symptoms and the appearance of nausea and vomiting. As obstruction progresses, the character of the vomitus alters from digested food to faeculent material, as a result of the presence of enteric bacterial overgrowth.

**Distension**

In the small bowel, the degree of distension is dependent on the site of the obstruction and is greater the more distal the lesion. Visible peristalsis may be present (Figure 70.7). This can sometimes be provoked by ‘flicking’ the abdominal wall. Distension is a later feature in colonic obstruction.

**Constipation**

This may be classified as absolute (i.e. neither faeces nor flatus is passed) or relative (where only flatus is passed). Absolute constipation is a cardinal feature of complete intestinal obstruction. Some patients may pass flatus or faeces after the onset of obstruction as a result of the evacuation of the distal bowel contents. The administration of enemas should be avoided in cases of suspected obstruction. This merely stimulates evacuation of bowel contents distal to the obstruction and confuses the clinical picture.

The rule that absolute constipation is present in intestinal obstruction does not apply in:
- Richter’s hernia;
- gallstone ileus;
- mesenteric vascular occlusion;
- functional obstruction associated with pelvic abscess;
- all cases of partial obstruction (in which diarrhoea may occur).

August Gottlieb Richter, 1742–1812, lecturer in surgery, Göttingen, Germany, described this form of hernia in 1777.
Clinical features of intestinal obstruction

Other manifestations

Dehydration
Dehydration is seen most commonly in small bowel obstruction because of repeated vomiting and fluid sequestration. It results in dry skin and tongue, poor venous filling and sunken eyes with oliguria. The blood urea level and haematocrit rise, giving a secondary polycythaemia.

Hypokalaemia
Hypokalaemia is not a common feature in simple mechanical obstruction. An increase in serum potassium, amylase or lactate dehydrogenase may be associated with the presence of strangulation, as may leukocytosis or leukopenia.

Pyrexia
Pyrexia in the presence of obstruction is rare and may indicate:
- The onset of ischaemia;
- Intestinal perforation;
- Inflammation or abscess associated with the obstructing disease.

Hypothermia indicates septicaemic shock or neglected cases of long duration.

Abdominal tenderness
Localised tenderness indicates impending or established ischaemia. The development of peritonism or peritonitis indicates impending or overt infarction and/or perforation. In cases of large bowel obstruction, it is important to elicit these findings in the right iliac fossa as the caecum is most vulnerable to ischaemia.

Bowel sounds
High-pitched bowel sounds are present in the vast majority of patients with intestinal obstruction. Normal bowel sounds are of negative predictive value. Bowel sounds may be scanty or absent if the obstruction is long-standing and the small bowel has become inactive.

Clinical features of strangulation
It is vital to distinguish strangulating from non-strangulating intestinal obstruction because the former is a surgical emergency. The diagnosis is almost entirely clinical; the clinical features are shown in Summary box 70.8.

Summary box 70.8

<table>
<thead>
<tr>
<th>Clinical features of strangulation</th>
</tr>
</thead>
<tbody>
<tr>
<td>▪ Constant pain, severe pain</td>
</tr>
<tr>
<td>▪ Tenderness with rigidity and peritonitis</td>
</tr>
<tr>
<td>▪ Shock</td>
</tr>
</tbody>
</table>

In addition to the features above, it should be noted that:
- The presence of shock suggests underlying ischaemia especially if the shock is resistant to simple fluid resuscitation.
- In impending or established strangulation, pain is never completely absent.
- The presence and character of any local tenderness are of great significance and, however mild, tenderness requires frequent reassessment.
- Generalised tenderness and the presence of rigidity indicate the need for early laparotomy.
- In cases of intestinal obstruction in which pain persists despite conservative management, even in the absence of the above signs, strangulation should be presumed.
- When strangulation occurs in an external hernia, the lump is tense, tender and irreducible and there is no expansile cough impulse. Skin changes with erythema or purplish discoloration are associated with underlying ischaemia (Figures 70.8 and 70.9).

Clinical features of intussusception
The classical presentation of intussusception is with episodes of screaming and drawing up of the legs in a previously well male infant. The attacks last for a few minutes and recur repeatedly. During attacks the child appears pale; between episodes he may be listless. Vomiting may or may not occur at the outset but becomes conspicuous and bile-stained with time. Initially, the passage of stool may be normal, whereas, later, blood and mucus are evacuated – the 'redcurrant jelly' stool.

Whenever possible, examination should be undertaken between episodes of colic, without disturbing the child. Classically, the abdomen is not initially distended; a lump that hardens on palpation may be discerned but this is present in only 60 per cent of cases (Figure 70.10). There may be an associated feeling of emptiness in the right iliac fossa (the sign of Dance). On rectal examination, blood-stained mucus may be found on the finger. Occasionally, in extensive ileocolic or colocolic...
Unrelieved, progressive dehydration and abdominal distension from small bowel obstruction will occur, followed by peritonitis secondary to gangrene. Rarely, natural cure may occur as a result of sloughing of the intussusception.

Differential diagnosis

Acute gastroenteritis
Although abdominal pain and vomiting are common in acute gastroenteritis, with occasional blood and mucus in the stool, diarrhoea is a leading symptom and faecal matter or bile is always present in the stool.

Henoch–Schöenlein purpura
Henoch–Schöenlein purpura is associated with a characteristic rash and abdominal pain; intussusception may occur.

Rectal prolapse
This may be easily differentiated by the fact that the projecting mucosa can be felt in continuity with the perianal skin whereas in intussusception the finger may pass indefinitely into the depths of a sulcus.

Clinical features of volvulus

Volvulus of the small intestine
This may be primary or secondary and usually occurs in the lower ileum. It may occur spontaneously in African people, particularly following the consumption of a large volume of vegetable matter, whereas in the West, it is usually secondary to adhesions passing to the parietes or female pelvic organs.

Caecal volvulus
This may occur as part of volvulus neonatorum or de novo and is usually a clockwise twist. It is more common in females in the fourth and fifth decades and usually presents acutely with the classic features of obstruction. Ischaemia is common. At first the obstruction may be partial, with the passage of flatus and faeces. In 25 per cent of cases, examination may reveal a palpable tympanic swelling in the midline or left side of the abdomen. The volvulus typically results in the caecum lying in the left upper quadrant. The diagnosis is not usually made preoperatively.

Sigmoid volvulus
The symptoms are of large bowel obstruction. Presentation varies in severity and acuteness, with younger patients appearing to develop the more acute form. Abdominal distension is an early and progressive sign, which may be associated with hiccup and retching. Constipation is absolute. In the elderly, a more chronic form may be seen. In some patients, the grossly distended torted left colon is visible through the abdominal wall.
Erect abdominal films are no longer routinely obtained and the radiological diagnosis is based on a supine abdominal film (Figure 70.11). An erect film may subsequently be requested when further doubt exists.

When distended with gas, the jejunum, ileum, caecum and remaining colon have a characteristic appearance in adults and older children that allows them to be distinguished radiologically (Summary box 70.9).

In intestinal obstruction, fluid levels appear later than gas shadows as it takes time for gas and fluid to separate (Figure 70.12). These are most prominent on an erect film. In adults, two inconstant fluid levels – one at the duodenal cap and the other in the terminal ileum – may be regarded as normal. In infants (less than one year old), a few fluid levels in the small bowel may be physiological. In this age group, it is difficult to distinguish large from small bowel in the presence of obstruction, because the characteristic features seen in adults are not present or are unreliable.

During the obstructive process, fluid levels become more conspicuous and more numerous when paralysis has occurred. When fluid levels are pronounced, the obstruction is advanced. In the small bowel, the number of fluid levels is directly proportional to the degree of obstruction and to its site, the number increasing the more distal the lesion.

In patients without evidence of strangulation, there is a role for other imaging modalities. A recent systematic review and meta-analysis of the diagnostic and therapeutic role of 50–100 mL water-soluble contrast agent in adhesive small bowel obstruction included 14 prospective studies. The appearance of contrast in the colon 4–24 hours after administration had a sensitivity of 96 per cent and a specificity of 98 per cent in predicting resolution of small bowel obstruction. If contrast does not reach the colon, surgery is required in about 90 per cent of patients. Administration of a water-soluble agent was also effective in reducing the need for surgery (OR 0.62; \( p = 0.007 \)) and shortening hospital stay.

In contrast, low colonic obstruction does not commonly give rise to small bowel fluid levels unless advanced, whereas high colonic obstruction may do so in the presence of an incompetent ileocaecal valve. Colonic obstruction is usually associated with a large amount of gas in the caecum. A limited water-soluble enema should be undertaken to differentiate large bowel obstruction from pseudo-obstruction. A barium follow-through is contraindicated in the presence of acute obstruction and may be life-threatening.

---

**Summary box 70.9**

**Radiological features of obstruction (on plain x-ray)**

- The obstructed small bowel is characterised by straight segments that are generally central and lie transversely. No/minimal gas is seen in the colon.
- The jejunum is characterised by its valvulae conniventes, which completely pass across the width of the bowel and are regularly spaced, giving a ‘concertina’ or ladder effect.
- Ileum – the distal ileum has been piquantly described by Wangensteen as featureless.
- Caecum – a distended caecum is shown by a rounded gas shadow in the right iliac fossa.
- Large bowel, except for the caecum, shows haustral folds, which, unlike valvulae conniventes, are spaced irregularly, do not cross the whole diameter of the bowel and do not have indentations placed opposite one another.

---

**Figure 70.11** Gas-filled small bowel loop; patient supine.

**Figure 70.12** Fluid levels with gas above; ‘stepladder pattern’. Ileal obstruction by adhesions; patient erect.

Owen Harding Wangensteen, 1898–1981, Professor of Surgery, The University of Minnesota, Minneapolis, MN, USA.
The CT scan is now used very widely to investigate all forms of intestinal obstruction. It is highly accurate and its only limitations are in diagnosing ischaemia. It is important to remember that even with the best imaging techniques, the diagnosis of strangulation remains a clinical one.

Impacted foreign bodies may be seen on abdominal radiographs. It is noteworthy that gas-filled loops and fluid levels in the small and large bowel can also be seen in established paralytic ileus and pseudo-obstruction. The former can, however, normally be distinguished on clinical grounds, whereas the latter can be confirmed radiologically. Fluid levels may also be seen in non-obstructing conditions such as gastroenteritis, acute pancreatitis and intra-abdominal sepsis.

**Imaging in intussusception**

A plain abdominal field usually reveals evidence of small or large bowel obstruction with an absent caecal gas shadow in ileocolic cases. A soft tissue opacity is often visible in children. A barium enema may be used to diagnose the presence of an ileocolic intussusception (the claw sign) (Figure 70.13), but does not demonstrate small bowel intussusception. An abdominal ultrasound scan has a high diagnostic sensitivity in children, demonstrating the typical doughnut appearance of concentric rings in transverse section. CT scan is currently considered the most sensitive radiologic method to confirm intussusception, with a reported diagnostic accuracy of 58–100 per cent. The characteristic features of CT scan include a ‘target’ or ‘sausage’-shaped soft-tissue mass with a layering effect, mesenteric vessels within the bowel lumen are also typical.

**Imaging in volvulus**

- In caecal volvulus, radiological abnormalities are identifiable in nearly all patients, but are often non-specific, with caecal dilatation (98–100 per cent), single air-fluid level (72–88 per cent), small bowel dilatation (42–55 per cent) and absence of gas in distal colon (82 per cent) reported as the most common abnormalities. A barium enema may be used to confirm the diagnosis if there are no concerns about ischaemia, with an absence of barium in the caecum and a bird beak deformity. CT scanning is replacing barium enema as the imaging of choice in these less urgent cases.

- In sigmoid volvulus, a plain radiograph shows massive colonic distension. The classic appearance is of a dilated loop of bowel, the two limbs are seen running diagonally across the abdomen from right to left, with two fluid levels seen, one within each loop of bowel (if an erect film is taken).

- In volvulus neonatorum, the abdominal radiograph shows a variable appearance. Initially, it may appear normal or show evidence of duodenal obstruction but, as the intestinal strangulation progresses, the abdomen becomes relatively gasless.

**TREATMENT OF ACUTE INTESTINAL OBSTRUCTION**

There are three main measures used to treat acute intestinal obstruction (Summary box 70.10).

---

**Summary box 70.10**

**Treatment of acute intestinal obstruction**

- Gastrointestinal drainage via a nasogastric tube
- Fluid and electrolyte replacement
- Relief of obstruction

Surgical treatment is necessary for most cases of intestinal obstruction but should be delayed until resuscitation is complete, provided there is no sign of strangulation or evidence of closed-loop obstruction.

The first two steps are always necessary before attempting the surgical relief of obstruction and are the mainstay of postoperative management.

The three principles of surgical intervention are shown in Summary box 70.11.

---

**Summary box 70.11**

**Principles of surgical intervention for obstruction**

Management of:

- The segment at the site of obstruction
- The distended proximal bowel
- The underlying cause of obstruction

**Supportive management**

Nasogastric decompression is achieved by the passage of a non-vented (Ryle) or vented (Salem) tube. The tubes are normally placed on free drainage with 4-hourly aspiration, but may be placed on continuous or intermittent suction. As well as facilitating decompression proximal to the obstruction, they are essential to reduce the risk of subsequent aspiration during induction of anaesthesia and post-extubation.

---

John Alfred Ryle, 1889–1950, Regius Professor of Physics, The University of Cambridge, and later Professor of Social Medicine, The University of Oxford, UK, introduced the Ryle’s tube in 1921.
The basic biochemical abnormality in intestinal obstruction is sodium and water loss, and therefore the appropriate replacement is Hartmann’s solution or normal saline. The volume required varies and should be determined by clinical haematological and biochemical criteria.

Antibiotics are not mandatory but many clinicians initiate broad-spectrum antibiotics early in therapy because of bacterial overgrowth. Antibiotic therapy is mandatory for all patients undergoing surgery for intestinal obstruction.

**Surgical treatment**

The timing of surgical intervention is dependent on the clinical picture. There are several indications for early surgical intervention (Summary box 70.12).

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

The classic clinical advice that ‘the sun should not both rise and set’ on a case of unrelied acute intestinal obstruction was based on the concern that intestinal ischaemia would develop while the patient was waiting for surgery. If there is complete obstruction, but no evidence of intestinal ischaemia, it is reasonable to defer surgery until the patient has been adequately resuscitated. Where obstruction is likely to be secondary to adhesions, conservative management may be continued for up to 72 hours in the hope of spontaneous resolution.

If the site of obstruction is unknown, adequate exposure is best achieved by a midline incision. Assessment is directed to:

- the site of obstruction;
- the nature of the obstruction;
- the viability of the gut.

In cases of small bowel obstruction, the first manoeuvre is to deliver the distended small bowel into the wound. This permits access to the site of obstruction. The small bowel should be covered with moist swabs and the weight of the fluid-filled bowel supported such that the blood supply to the mesentery is not impaired.

**Operative decompression** should be performed whenever possible. This reduces pressure on the abdominal wound reducing pain and improving diaphragmatic movement. The simplest and safest method is to insert a large bore orogastric tube and to milk the small bowel contents in a retrograde manner to the stomach for aspiration. All volumes of fluid removed should be accurately measured and appropriately replaced. It is important to ensure that the stomach is empty at the end of the procedure to prevent postoperative aspiration.

Rarely, decompression using Savage’s decompressor within a seromuscular purse-string suture may be required. Its benefits should be balanced against the potential risk of septic complications from spillage and the risk of leakage from the suture line postoperatively. The type of surgical procedure required will depend upon the cause of obstruction – division of adhesions (enterolysis), excision, bypass or proximal decompression.

Following relief of obstruction, the viability of the involved bowel should be carefully assessed (Table 70.3). Although frankly infarcted bowel is obvious, the viability status in many cases may be difficult to discern. In doubt, the bowel should be wrapped in hot packs for 10 minutes with increased oxygenation and then reassessed. The state of the mesenteric vessels and pulsation in adjacent arcades should be sought. Viability is also confirmed by colour, sheen and peristalsis. If at the end of this period, there is still uncertainty about gut viability, the gut should be resected if this does not result in short bowel syndrome. If the patient is septic such that they require isotropic therapy or would require postoperative level 3 intensive care treatment following resection, consideration should be given to raising both ends of the bowel as stomas. This is not only safe, but also allows regular assessment of the bowel.

Intestinal ischaemia/reperfusion injury has been described following reperfusion of ischaemic bowel with remote lung injury resulting from the release of inflammatory mediators. This should be borne in mind when dealing with ischaemic bowel. For example, if there is a volvulus with established infarction, detorsion should be avoided until the affected mesentery has been clamped and thus reperfusion injury prevented. When no resection has been undertaken or there are multiple ischaemic areas (mesenteric vascular occlusion), a second-look laparotomy at 24–48 hours may be required.

Special attention should always be paid to the sites of constriction at each end of an obstructed segment. If of doubtful viability they should be infolded by the use of a seromuscular suture and can also be covered with omentum (Figures 70.14 and 70.15).

The surgical management of massive infarction is dependent on the patient’s overall prognostic criteria. In the elderly, infarction of the small bowel from the duodenojejunal flexure to the right colon may be considered incurable, whereas in the young, with the potential for long-term intravenous alimentation and small bowel transplantation, a policy of excision may be justified.

Whenever the small bowel is resected, the exact site of resection, the length of the resected segment and that of the residual bowel should be recorded.

*Paul Thwaites Savage, formerly surgeon, The Whittington Hospital, London, UK.*
As laparoscopic surgery is now so common, it is important to note that small bowel obstruction and strangulation occur in relation to port site hernias. The risk of port site herniation is related to older age, higher body mass, trocar diameter and extension of the port site for tissue extraction. For laparoscopic cholecystectomy, the hernia rate is reported to be around 2 per cent. Obstruction and strangulation have even been reported through 5-mm port sites. Complications from these hernias may present in the early postoperative period and as a Richter's hernia. They can be easily overlooked and careful examination of port sites in patients with small bowel obstruction is essential.

**Treatment of adhesions**

Initial management is based on intravenous rehydration and nasogastric decompression; occasionally, this treatment is curative. Although an initial conservative regimen is considered appropriate, regular assessment is mandatory to ensure that strangulation does not occur. Conservative treatment should not usually be prolonged beyond 72 hours.

When laparotomy is required, although multiple adhesions may be found, only one may be causative. If there is absolute certainty that this is the cause of the obstruction, this should be divided and the remaining adhesions can be left in situ unless severe angulation is present. Division of these adhesions will only cause further adhesion formation.

When obstruction is caused by an area of multiple adhesions, the adhesions should be freed by sharp dissection from the duodeno-jejunal junction to the caecum. Following the release of band obstruction, the constriction sites that have suffered direct compression should be carefully assessed and, if they show residual colour changes, invaginated with a seromuscular suture (Figure 70.15).

Laparoscopic adhesiolysis may be considered in highly selected cases of small bowel obstruction (Summary box 70.13). This is classed as an advanced laparoscopic procedure and should only be undertaken by surgeons with advanced laparoscopic skills.

**Summary box 70.13**

**Treatment of adhesive obstruction**

- Initially treat conservatively provided there are no signs of strangulation; should rarely continue conservative treatment for longer than 72 hours
- At operation, divide only the causative adhesion(s) and limit dissection
- Repair serosal tears; invaginate (or resect) areas of doubtful viability
- Laparoscopic adhesiolysis in the hands of advanced laparoscopic practitioners
Treatment of recurrent intestinal obstruction caused by adhesions

Several procedures may be considered in the presence of recurrent obstruction including:

- repeat adhesiolysis (enterolysis) alone;
- Noble’s plication operation;
- Charles–Phillips transmesenteric plication;
- intestinal intubation.

The latter three operations are now very rarely performed and can probably be consigned to the history books (they have never been required by the author).

Postoperative intestinal obstruction

Differentiation between persistent paralytic ileus and early mechanical obstruction may be difficult in the early postoperative period. Mechanical obstruction is more likely if the patient has regained bowel function postoperatively which subsequently stops. Obstruction is usually incomplete and the majority settle with continued conservative management. Postoperative intra-abdominal sepsis is a potent cause of postoperative obstruction; CT scanning with oral contrast is of particular value in the assessment of the postoperative abdomen. A water-soluble contrast agent (50–100mL) by mouth with a delayed plain abdominal x-ray is also of value (see p. 1189).

Treatment of intussusception

In the infant with ileocolic intussusception, after resuscitation with intravenous fluids, broad-spectrum antibiotics and nasogastric drainage, non-operative reduction can be attempted using an air or barium enema (see Chapter 8, Figure 6.17). Successful reduction can only be accepted if there is free reflux of air or barium into the small bowel, together with resolution of symptoms and signs in the patient. Non-operative reduction is contraindicated if there are signs of peritonitis or perforation, there is a known pathological lead point or in the presence of profound shock. In experienced units, more than 70 per cent of intussusceptions can be reduced non-operatively. Strangulated bowel and pathological lead points are unlikely to reduce. Perforation of the colon during pneumatic or hydrostatic reduction is a recognised hazard, but is rare. Recurrent intussusception occurs in up to 10 per cent of patients after non-operative reduction.

Surgery is required when radiological reduction has failed or is contraindicated. After resuscitation, a transverse right-sided abdominal incision provides good access. Reduction is achieved by gently compressing the most distal part of the intussusception toward its origin (Figure 70.16), making sure not to pull. The last part of the reduction is the most difficult (Figure 70.17). After reduction, the terminal part of the small bowel and the appendix will be seen to be bruised and oedematous. The viability of the whole bowel should be checked carefully. An irreducible intussusception or one complicated by infarction or a pathological lead point requires resection and primary anastomosis.

Acute intestinal obstruction of the newborn

Neonatal intestinal obstruction has many potential causes. Congenital atresia and stenosis are the most common.

![Figure 70.16 Diagram showing the method used to reduce an intussusception.](image1)

![Figure 70.17 Reducing the terminal part of the intussusception (after RE Gross).](image2)

Intestinal malrotation with midgut volvulus, meconium ileus, Hirschsprung’s disease, imperforate anus, necrotising enterocolitis and an incarcerated inguinal hernia may also be responsible. Many of these conditions are discussed in Chapter 8.

Intestinal atresia

Duodenal atresia and stenosis are the most common forms of intestinal obstruction in the newborn (see Chapter 8). Jejunal or ileal atresias are next in frequency, whereas colonic atresia is rare. The possibility of multiple atresias makes intraoperative assessment of the whole small and large bowel mandatory. As with all congenital anomalies, associated malformations are common and should be excluded.

There are four main types of jejunal/ileal atresia, ranging from an obstructing membrane with continuity of the bowel wall, through blind-ended segments of bowel separated by a fibrous cord or V-shaped mesenteric defect (including the so-called apple-peel atresia) (Figure 70.18), to multiple atresias (‘string of sausages’). The obstructed proximal bowel is at risk of perforation, which may happen prenatally causing meconium peritonitis in the fetus.

Small bowel atresias present with intestinal obstruction soon after birth. Bilious vomiting is the dominant feature in jejunal atresia, whereas abdominal distension is more prominent with...

Thomas Benjamin Noble, 1895–1965, surgeon, The Community Hospital, Indianapolis, IN, USA.
Richard V Phillips, surgeon, Albuquerque, NM, USA.
Friedrich Oskar Witzel, 1856–1925, a surgeon in Bonn, Germany.
ileal atresia. A small amount of pale meconium may be passed despite the atresia.

Plain abdominal radiographs show a variable number of dilated loops of bowel and fluid levels according to the level of obstruction. In a stable infant, a contrast enema may be required to clarify the cause of a distal bowel obstruction.

Surgery
Duodenal atresia is corrected by a duodenoduodenostomy. In most cases of jejunal/ileal atresia, the distal end of the dilated proximal small bowel is resected and a primary end-to-end anastomosis is possible. If the proximal bowel is extremely dilated it may need to be tapered to the distal bowel before anastomosis. Occasionally, a temporary stoma is required before definitive repair.

Meconium ileus
Cystic fibrosis is almost always the underlying cause of this condition. Meconium is normally kept fluid by the action of pancreatic enzymes. In meconium ileus, the terminal ileum becomes filled with thick viscid meconium, resulting in progressive intestinal obstruction. A sterile meconium peritonitis may have occurred in utero.

Visibly dilated loops of bowel are often palpable in the newborn with meconium ileus. An abdominal radiograph may show a dilated small intestine with motting. Fluid levels are generally not seen. Unlike ileal atresia there is no abrupt termination of the gas-filled intestine. A contrast enema shows an unused microcolon. As the condition is caused by an autosomal recessive genetic defect, a family history may not be present. Further assessment includes gene mutation analysis and, beyond the neonatal period, a sweat test, which shows elevated sodium and chloride levels (>70 mmol/L).

Uncomplicated meconium ileus may respond to treatment with a hyperosmolar gastrografin enema. This draws fluid into the gut lumen and also has detergent properties, which help to liquefy the meconium. Infants treated in this way need extra intravenous fluids to compensate for fluid shifts. Meconium ileus complicated by intestinal perforation, volvulus or atresia, or unresponsive to enemas, demands surgery. Various surgical procedures are used including intestinal resection and temporary stoma formation, resection and primary anastomosis, and, in uncomplicated cases, enterostomy and irrigation of the bowel. The Bishop–Koop operation (Figure 70.19) with its irrigating stoma is now only rarely used.

**TREATMENT OF ACUTE LARGE BOWEL OBSTRUCTION**

Large bowel obstruction is usually caused by an underlying carcinoma or occasionally diverticular disease, and presents in an acute or chronic form. The condition of pseudo-obstruction should always be considered and excluded by a limited contrast study or CT scan to confirm organic obstruction.

After full resuscitation, the abdomen should be opened through a midline incision. Care should be taken to ensure that the loss of tamponade of the abdominal wall does not lead to increased caecal distension and rupture (this starts with splitting along the line of the taenia coli on the antimesenteric border). Distension of the caecum will confirm large bowel involvement. Identification of a collapsed distal segment of the large bowel and its sequential proximal assessment will readily lead to identification of the cause. As surgery for malignant bowel cancer is technically challenging, wherever possible a suitably trained surgeon should perform the procedure. When a removable lesion is found in the caecum, ascending colon, hepatic flexure or proximal transverse colon, an emergency right hemicolectomy should be performed. A primary anastomosis is safe if the patient’s general condition is reasonable. If the lesion is irremovable (this is rarely the case), a proximal stoma (colostomy or ileostomy if the ileocaecal valve is incompetent) or ileotransverse bypass should be considered. Obstructing lesions at the splenic flexure should be treated by an extended right hemicolectomy with ileo-descending colonic anastomosis.
For obstructing lesions of the left colon or rectosigmoid junction, immediate resection should be considered unless there are clear contraindications (Summary box 70.14).

Summary box 70.14

Management of left-sided large bowel obstruction

Contraindications to immediate resection include:

- Inexperienced surgeon
- Moribund patient
- Advanced disease

In rare instances, or when caecal perforation is imminent, additional time to improve the patient's clinical condition can be bought by performing an emergency caecostomy (or ileostomy in the presence of an incompetent ileocaecal valve).

In the absence of senior clinical staff, it is safest to bring the proximal colon to the surface as a colostomy. When possible, the distal bowel should be brought out at the same time (Paul–Mikulicz procedure) to facilitate subsequent closure. In the majority of cases, the distal bowel will not reach and is closed and returned to the abdomen (Hartmann’s procedure). A second-stage colorectal anastomosis can be planned when the patient is fit.

If an anastomosis is to be considered using the proximal colon, in the presence of obstruction, it must be decompressed and cleaned by an on-table colonic lavage.

Decompression of the obstructed left colon using endoscopically placed stents often as a bridge to surgery has been widely reported. However, as yet randomised trials have not shown improved outcomes compared to standard surgical treatment (Figure 70.20).

Treatment of caecal volvulus

At operation, the volvulus is usually found to be ischaemic and needs resection. If, viable, the volvulus should be reduced. Sometimes, this can only be achieved after decompression of the caecum using a needle. Further management consists of fixation of the caecum to the right iliac fossa (caecopexy) and/or a caecostomy. Recurrence of volvulus after caecopexy has been reported in up to 40 per cent of cases.

Treatment of sigmoid volvulus

Flexible sigmoidoscopy or rigid sigmoidoscopy and insertion of a flatus tube should be carried out to allow deflation of the gut. The tube should be secured in place with tape for 24 hours and a repeat x-ray taken to ensure that decompression has occurred. Successful deflation, as long as ischaemic bowel is excluded, will resolve the acute problem.

In young patients, an elective sigmoid colectomy is required. It is reasonable not to offer any further treatment following successful endoscopic decompression in the elderly as there is a high death rate (~80 per cent at two years) from causes other than recurrent volvulus. In elderly patients with comorbidities and recurrent episodes of volvulus, the options are resection or two point fixation with combined endoscopic/percutaneous tube insertion (gastrostomy tubes are frequently used for this purpose). Failure results in an early laparotomy, with untwisting of the loop and per anum decompression (Figure 70.21). When the bowel is viable, fixation of the sigmoid colon to the posterior abdominal wall may be a safer manoeuvre in inexperienced hands. Resection is preferable if it can be achieved.
ABDOMINAL INTESTINAL OBSTRUCTION

safely. A Paul–Mikulicz procedure is useful, particularly if there is suspicion of impending gangrene (Figure 70.22); an alternative procedure is a sigmoid colectomy and, when anastomosis is considered unwise, a Hartmann’s procedure with subsequent reanastomosis can be carried out.

CHRONIC LARGE BOWEL OBSTRUCTION

The symptoms of chronic intestinal obstruction may arise from two sources – the cause and the subsequent obstruction.

The causes of obstruction may be organic:

- intraluminal (rare) – faecal impaction;
- intrinsic intramural – strictures (Crohn’s disease, ischaemia, diverticular), anastomotic stenosis;
- extrinsic intramural (rare) – metastatic deposits (ovarian), endometriosis, stomal stenosis;

or functional:

- Hirschsprung’s disease, idiopathic megacolon, pseudo-obstruction.

The symptoms of chronic obstruction differ in their predomiance, timing and degree from acute obstruction. In functional cases, the symptoms may have been present for months or years. Constipation appears first. It is initially relative and then absolute, associated with distension. In the presence of large bowel disease, the point of greatest distension is in the caecum, and this is heralded by the onset of pain. Vomiting is a late feature and therefore dehydration is less severe. Examination is unremarkable, save for confirmation of distension (which can be profound) (Figure 70.23) and the onset of peritonism in late cases. Rectal examination may confirm the presence of faecal impaction or a tumour.

Investigation

Plain abdominal radiography confirms the presence of large bowel distension. All such cases should be investigated by a subsequent single-contrast water-soluble enema study, CT scan or endoscopic assessment to rule out functional disease (Summary box 70.15).

Figure 70.22 The Paul–Mikulicz operation applied to volvulus of the pelvic colon.

Figure 70.23 Gross functional distension.

Summary box 70.15

Principles of investigation of possible large bowel obstruction

- In the presence of large bowel obstruction, a single contrast water-soluble enema or CT should be undertaken to exclude a functional cause

**Organic disease** requires decompression with either a laparotomy or stent. Stomal stenosis can usually be managed at the abdominal wall level (Figure 70.24). Surgical management after resuscitation depends on the underlying cause and the relevant chapters in this book should be consulted.

Frank Thomas Paul, 1851–1941, surgeon, The Royal Infirmary, Liverpool, UK
Johann von Mikulicz-Radecki, 1850–1905, Professor of Surgery, Breslau, Germany (now Wroclaw, Poland)
Functional disease requires colonoscopic decompression in the first instance and conservative management. Intestinal perforation can occur in patients with functional obstruction. Those at risk have such gross distension that the abdomen is rigid on palpation (Figure 70.23).

**ADYNAMIC OBSTRUCTION**

**Paralytic ileus**

This may be defined as a state in which there is failure of transmission of peristaltic waves secondary to neuromuscular failure (i.e. in the myenteric (Auerbach’s) and submucous (Meissner’s) plexuses). The resultant stasis leads to accumulation of fluid and gas within the bowel, with associated distension, vomiting, absence of bowel sounds and absolute constipation.

**Varieties**

The following varieties are recognised:

- **Postoperative.** A degree of ileus usually occurs after any abdominal procedure and is self-limiting, with a variable duration of 24–72 hours. Postoperative ileus may be prolonged in the presence of hypoproteinaemia or metabolic abnormality (see below).
- **Infection.** Intra-abdominal sepsis may give rise to localised or generalised ileus.
- **Reflex ileus.** This may occur following fractures of the spine or ribs, retroperitoneal haemorrhage or even the application of a plaster jacket.
- **Metabolic.** Uraemia and hypokalaemia are the most common contributory factors.

**Clinical features**

Paralytic ileus takes on a clinical significance if, 72 hours after laparotomy:

- there has been no return of bowel sounds on auscultation;
- there has been no passage of flatus.

Abdominal distension becomes more marked and tympanitic. Colicky pain is not a feature. Distension increases pain from the abdominal wound. In the absence of gastric aspiration, effortless vomiting may occur. Radiologically, the abdomen shows gas-filled loops of intestine with multiple fluid levels (if an erect film is felt necessary).

**Management**

Nasogastric tubes are not required routinely after elective intra-abdominal surgery. Paralytic ileus is managed with the use of nasogastric suction and restriction of oral intake until bowel sounds and the passage of flatus return. Electrolyte balance must be maintained. The use of an enhanced recovery programme with early introduction of fluids and solids is, however, becoming increasingly popular.

Specific treatment is directed towards the cause, but the following general principles apply:

- If a primary cause is identified, this must be treated.
- Gastrointestinal distension must be relieved by decompression.
- Close attention to fluid and electrolyte balance is essential.
- There is no place for the routine use of peristaltic stimulants. Rarely, in resistant cases, medical therapy with a gastroprokinetic agent, such as domperidone or erythromycin may be used, provided that an intraperitoneal cause has been excluded.

- If paralytic ileus is prolonged, CT scanning is the most effective investigation; it will demonstrate any intra-abdominal sepsis or mechanical obstruction and therefore guide any requirement for laparotomy. Otherwise the decision to take a patient back to theatre in these circumstances is always difficult. The need for a laparotomy becomes increasingly likely the longer the bowel inactivity persists, particularly if it lasts for more than 7 days or if bowel activity recommences following surgery and then stops again.

**Pseudo-obstruction**

This condition describes an obstruction, usually of the colon, that occurs in the absence of a mechanical cause or acute intra-abdominal disease. It is associated with a variety of syndromes in which there is an underlying neuropathy and/or myopathy and a range of other factors (Summary box 70.16).

**Small intestinal pseudo-obstruction**

This condition may be primary (i.e. idiopathic or associated with familial visceral myopathy) or secondary. The clinical picture consists of recurrent subacute obstruction. The diagnosis is made by the exclusion of a mechanical cause. Treatment consists of initial correction of any underlying disorder. Metoclopramide and erythromycin may be of use.

---

Leopold Auerbach, 1828–1897, Professor of Neuropathology, Breslau, Germany (now Wroclaw, Poland), described the myenteric plexus in 1862.

Georg Meissner, 1829–1905, Professor of Physiology, Gießen, Germany, described the submucous plexus of the alimentary tract in 1852.

Carlos Justiniano Ribeiro Chagas, 1879–1934, Director of The Oswaldo Cruz Institute, and Professor of Tropical Medicine, The University of Rio de Janeiro, Brazil.

Colonic pseudo-obstruction

This may occur in an acute or a chronic form. The former, also known as Ogilvie’s syndrome, presents as acute large bowel obstruction. Abdominal radiographs show evidence of colonic obstruction, with marked caecal distension being a common feature. Indeed, caecal perforation is a well-recognised complication. The absence of a mechanical cause requires urgent confirmation by colonoscopy or a single-contrast water-soluble barium enema or CT. Once confirmed, pseudo-obstruction requires treatment of any identifiable cause. If this is ineffective, intravenous neostigmine should be given (1 mg intravenously), with a further 1 mg given intravenously within a few minutes if the first dose is ineffective. During this procedure, it is best to sit the patient on a commode. ECG monitoring is required and atropine should be available. If neostigmine is not effective, colonoscopic decompression should be performed. Caecal perforation can occur in pseudo-obstruction. Abdominal examination should pay attention to tenderness and peritonism over the caecum and as with mechanical obstruction, caecal perforation is more likely if the caecal diameter is 14 cm or greater. Surgery is associated with high morbidity and mortality and should be reserved for those with impending perforation when other treatments have failed or perforation has occurred.

Rarely, an endoscopically placed tube colostomy is used as a vent for patients with those with a chronic unremitting condition.

FURTHER READING

ABDOMINAL
CHAPTER

INTRODUCTION

The vermiform appendix is considered by most to be a vestigial organ; its importance in surgery results only from its propensity for inflammation, which results in the clinical syndrome known as ‘acute appendicitis’. Acute appendicitis is the most common cause of an ‘acute abdomen’ in young adults and, as such, the associated symptoms and signs have become a paradigm for clinical teaching. Appendicitis is sufficiently common that appendicectomy (termed ‘appendectomy’ in North America) is the most frequently performed urgent abdominal operation and is often the first major procedure performed by a surgeon in training. Advances in modern radiographic imaging have improved diagnostic accuracy, however the diagnosis of appendicitis remains essentially clinical, requiring a mixture of observation, clinical acumen and surgical science and as such it remains an enigmatic challenge and a reminder of the art of surgical diagnosis.

ANATOMY

The vermiform appendix is present only in humans, certain anthropoid apes and the wombat. It is a blind muscular tube with mucosal, submucosal, muscular and serosal layers. Morphologically, it is the undeveloped distal end of the large caecum found in many lower animals. At birth, the appendix is short and broad at its junction with the caecum, but differential growth of the caecum produces the typical tubular structure by about the age of two years (Condon). During childhood, continued growth of the caecum commonly rotates the appendix into a retrocaecal but intraperitoneal position (Figure 71.1). In approximately one quarter of cases, rotation of the appendix does not occur, resulting in a pelvic, subcaecal or paracaecal position. Occasionally, the tip of the appendix becomes extraperitoneal, lying behind the caecum or ascending colon. Rarely, the caecum does not migrate during development to its normal position in the right lower quadrant of the abdomen. In these circumstances, the appendix can be found near the gall bladder or, in the case of intestinal malrotation, in the left iliac fossa, causing diagnostic difficulty if appendicitis develops (Figure 71.2).

The position of the base of the appendix is constant, being found at the confluence of the three taeniae coli of the caecum, which fuse to form the outer longitudinal muscle coat of the appendix. At operation, use can be made of this to find an elusive appendix, as gentle traction on the taeniae coli, particularly the anterior taenia, will lead the operator to the base of the appendix.

The mesentery of the appendix or mesoappendix arises from the lower surface of the mesentery or the terminal ileum and is itself subject to great variation. Sometimes, as much as the

LEARNING OBJECTIVES

To understand:
- The aetiology and surgical anatomy of acute appendicitis
- The clinical signs and differential diagnoses of appendicitis
- The investigation of suspected appendicitis

- Evolving concepts in management of acute appendicitis
- Basic surgical techniques, both open and laparoscopic
- The management of postoperative problems
- Less common conditions encountered

A wombat is a nocturnal burrowing Australian marsupial.

Robert E Condon, contemporary, Emeritus Professor of Surgery, The Medical College of Wisconsin, WI, USA.

Figure 71.1 The various positions of the appendix (after Sir C Wakeley, London, formerly PRCS).
The distal one-third of the appendix is bereft of mesoappendix. Especially in childhood, the mesoappendix is so transparent that the contained blood vessels can be seen (Figure 71.3). In many adults, it becomes laden with fat, which obscures these vessels. The appendicular artery, a branch of the lower division of the ileocolic artery, passes behind the terminal ileum to enter the mesoappendix a short distance from the base of the appendix. It then comes to lie in the free border of the mesoappendix. An accessory appendicular artery may be present but, in most people, the appendicular artery is an 'end-artery', thrombosis of which results in necrosis of the appendix (synonym: gangrenous appendicitis). Four, six or more lymphatic channels traverse the mesoappendix to empty into the ileocaecal lymph nodes.

**Microscopic anatomy**

The appendix varies considerably in length and circumference. The average length is between 7.5 and 10 cm. The lumen is irregular, being encroached upon by multiple longitudinal folds of mucous membrane lined by columnar cell intestinal mucosa of colonic type (Figure 71.4). Crypts are present, but are not numerous. In the base of the crypts lie argentaffin cells (Kulchitsky cells), which may give rise to carcinoid tumours (see below under Carcinoid tumours). The appendix is the most frequent site for carcinoid tumours, which may present with appendicitis due to occlusion of the appendiceal lumen. The submucosa contains numerous lymphatic aggregations or follicles. While no discernible change in immune function results from appendicectomy, the prominence of lymphatic tissue in the appendix of young adults seems to be important in the aetiology of appendicitis (see below under Aetiology).

**ACUTE APPENDICITIS**

While there are isolated reports of perityphlitis (fatal inflammation of the caecal region) from the late 1500s, recognition of acute appendicitis as a clinical entity is attributed to Reginald Fitz, who presented a paper to the first meeting of the Association of American Physicians in 1886 entitled ‘Perforating inflammation of the vermiform appendix’. Soon afterwards, Charles McBurney described the clinical manifestations of acute appendicitis including the point of maximum tenderness in the right iliac fossa that now bears his name.

The incidence of appendicitis seems to have risen greatly in the first half of the twentieth century, particularly in Europe, America and Australasia, with up to 16 per cent of the population undergoing appendicectomy. In the past 30 years, the
incidence has fallen dramatically in these countries, such that the individual lifetime risk of appendicectomy is 8.6 and 6.7 per cent among males and females, respectively.

Acute appendicitis is relatively rare in infants, and becomes increasingly common in childhood and early adult life, reaching a peak incidence in the teens and early 20s. After middle age, the risk of developing appendicitis is quite small. The incidence of appendicitis is equal among males and females before puberty. In teenagers and young adults, the male–female ratio increases to 3:2 at age 25; thereafter, the greater incidence in males declines.

**Aetiology**

There is no unifying hypothesis regarding the aetiology of acute appendicitis. Decreased dietary fibre and increased consumption of refined carbohydrates may be important. As with colonic diverticulitis, the incidence of appendicitis is lowest in societies with a high dietary fibre intake. In developing countries that are adopting a more refined western-type diet, the incidence continues to rise. This is in contrast to the dramatic decrease in the incidence of appendicitis in western countries observed in the past 30 years. No reason has been established for these paradoxical changes; however, improved hygiene and a change in the pattern of childhood gastrointestinal infection related to the increased use of antibiotics may be responsible.

While appendicitis is clearly associated with bacterial proliferation within the appendix, no single organism is responsible. A mixed growth of aerobic and anaerobic organisms is usual. The initiating event causing bacterial proliferation is controversial. Obstruction of the appendix lumen has been widely held to be important, and some form of luminal obstruction, either by a faecolith or a stricture, is found in the majority of cases.

A faecolith (sometimes referred to as an ‘appendicolith’) is composed of inspissated faecal material, calcium phosphates, bacteria and epithelial debris (Figure 71.5). Rarely, a foreign body is incorporated into the mass. The incidental finding of a faecolith is a relative indication for prophylactic appendicectomy or an interval appendicectomy in a patient treated conservatively (see below) (Figure 71.6). A fibrotic stricture of the appendix usually indicates previous appendicitis that resolved without surgical intervention (Figure 71.7). Obstruction of the appendiceal orifice by tumour, particularly carcinoma of the caecum, is an occasional cause of acute appendicitis in middle-aged and elderly patients. Intestinal parasites, particularly *Oxyurus vermicularis* (pinworm), can proliferate in the appendix and occlude the lumen.

**Pathology**

Obstruction of the appendiceal lumen seems to be essential for the development of appendiceal gangrene and perforation. Yet, in many cases of early appendicitis, the appendix lumen is patent despite the presence of mucosal inflammation and lymphoid hyperplasia. Occasional clustering of cases among children and young adults suggests an infective agent, possibly viral, which initiates an inflammatory response. Seasonal variation in the incidence is also observed, with more cases occurring between May and August in Northern Europe than at other times of the year.
Lymphoid hyperplasia narrows the lumen of the appendix, leading to luminal obstruction. Once obstruction occurs, continued mucus secretion and inflammatory exudation increase intraluminal pressure, obstructing lymphatic drainage. Oedema and mucosal ulceration develop with bacterial translocation to the submucosa. Resolution may occur at this point either spontaneously or in response to antibiotic therapy. If the condition progresses, further distension of the appendix may cause venous obstruction and ischaemia of the appendix wall. With ischaemia, bacterial invasion occurs through the muscularis propria and submucosa, producing acute appendicitis (Figure 71.8). Finally, ischaemic necrosis of the appendix wall produces gangrenous appendicitis, with free bacterial contamination of the peritoneal cavity. Alternatively, the greater omentum and loops of small bowel become adherent to the inflamed appendix, walling off the spread of peritoneal contamination, and resulting in a phlegmonous mass or paracæcal abscess. Rarely, appendiceal inflammation resolves, leaving a distended mucus-filled organ termed a ‘mucocoele’ of the appendix (Figure 71.9).

It is the potential for diffuse peritonitis that is the great threat of acute appendicitis. Peritonitis occurs as a result of free migration of bacteria through an ischaemic appendicular wall, frank perforation of a gangrenous appendix or delayed perforation of an appendix abscess. Factors that promote this process include extremes of age, immunosuppression, diabetes mellitus and faecolith obstruction of the appendix lumen, a free-lying pelvic appendix and previous abdominal surgery that limits the ability of the greater omentum to wall off the spread of peritoneal contamination. In these situations, a rapidly deteriorating clinical course is accompanied by signs of diffuse peritonitis and systemic sepsis syndrome (Summary box 71.1).

**Summary box 71.1**

**Risk factors for perforation of the appendix**
- Extremes of age
- Immunosuppression
- Diabetes mellitus
- Faecolith obstruction
- Pelvic appendix
- Previous abdominal surgery

**Clinical diagnosis**

**History**
The classical features of acute appendicitis begin with poorly localised colicky abdominal pain. This is due to midgut visceral...
discomfort in response to appendical inflammation and obstruction. The pain is frequently first noticed in the periumbilical region and is similar to, but less intense than, the colic of small bowel obstruction. Central abdominal pain is associated with anorexia, nausea and usually one or two episodes of vomiting that follow the onset of pain (Murphy). Anorexia is a useful and constant clinical feature, particularly in children. The patient often gives a history of similar discomfort that settled spontaneously. A family history is also useful as up to one-third of children with appendicitis have a first-degree relative with a similar history (Summary box 71.2).

Summary box 71.2

**Symptoms of appendicitis**

- Periumbilical colic
- Pain shifting to the right iliac fossa
- Anorexia
- Nausea

With progressive inflammation of the appendix, the parietal peritoneum in the right iliac fossa becomes irritated, producing more intense, constant and localised somatic pain that begins to predominate. Patients often report this as an abdominal pain that has shifted and changed in character. Typically, coughing or sudden movement exacerbates the right iliac fossa pain.

The classic visceral–somatic sequence of pain is present in only about half of those patients subsequently proven to have acute appendicitis. Atypical presentations include pain that is predominantly somatic or visceral and poorly localised. Atypical pain is more common in the elderly, in whom localisation to the right iliac fossa is unusual. An inflamed appendix in the pelvis may never produce somatic pain involving the anterior abdominal wall, but may instead cause suprapubic discomfort and tenesmus. In this circumstance, tenderness may be elicited only on rectal examination and is the basis for the recommendation that a rectal examination should be performed on every patient who presents with acute lower abdominal pain.

During the first 6 hours, there is rarely any alteration in temperature or pulse rate. After that time, slight pyrexia (37.2–37.7°C) with a corresponding increase in the pulse rate to 80 or 90 is usual. However, in 20 per cent of patients, there is no pyrexia or tachycardia in the early stages. In children, a temperature greater than 38.5°C suggests other causes, e.g. mesenteric adenitis (see below under Children).

Typically, two clinical syndromes of acute appendicitis can be discerned, **acute catarrhal** (non-obstructive) appendicitis and **acute obstructive** appendicitis, the latter characterised by a more acute course. The onset of symptoms is abrupt, and there may be generalised abdominal pain from the start. The temperature may be normal and vomiting is common, so that the clinical picture may mimic acute intestinal obstruction.

**Signs**

The diagnosis of appendicitis rests more on thorough clinical examination of the abdomen than on any aspect of the history or laboratory investigation. The cardinal features are those of an unwell patient with low-grade pyrexia, localised abdominal tenderness, muscle guarding and rebound tenderness. Inspection of the abdomen may show limitation of respiratory movement in the lower abdomen. The patient is then asked to point to where the pain began and where it moved (the pointing sign). Gentle superficial palpation of the abdomen, beginning in the left iliac fossa moving anticlockwise to the right iliac fossa will detect muscle guarding over the point of maximum tenderness, classically McBurney’s point. Asking the patient to cough or gentle percussion over the site of maximum tenderness will elicit rebound tenderness (Summary box 71.3).

Summary box 71.3

**Clinical signs in appendicitis**

- Pyrexia
- Localised tenderness in the right iliac fossa
- Muscle guarding
- Rebound tenderness

Deep palpation of the left iliac fossa may cause pain in the right iliac fossa, Rovsing’s sign, which is helpful in supporting a clinical diagnosis of appendicitis. Occasionally, an inflamed appendix lies on the psoas muscle, and the patient, often a young adult, will lie with the right hip flexed for pain relief (the psoas sign). Spasm of the obturator internus is sometimes demonstrable when the hip is flexed and internally rotated. If an inflamed appendix is in contact with the obturator internus, this manoeuvre will cause pain in the hypogastrium (the obturator test; Zachary Cope). Cutaneous hyperaesthesia may be demonstrable in the right iliac fossa, but is rarely of diagnostic value (Summary box 71.4).

Summary box 71.4

**Signs to elicit in appendicitis**

- Pointing sign
- Rovsing’s sign
- Psoas sign
- Obturator sign

Charles McBurney, 1854–1913, Professor of Surgery, Columbia College of Physicians and Surgeons, New York, NY, USA. In 1889, McBurney published a paper on appendicitis in which he stated ‘I believe in every case the seat of greatest pain determined by the pressure of one finger has been very exactly between an inch and a half and two inches from the anterior spurious process of the ilium on a straight line drawn from that process to the umbilicus.’

Sir Vincent Zachary Cope, 1881–1975, surgeon, St Mary’s Hospital, London, UK. He was a poet who wrote a poetry book under a pseudonym ‘Zeta’ describing the acute abdomen: ‘The Acute Abdomen in Rhyme’. He described the differential diagnosis of acute appendicitis as:

- Distension, rigidity, vomiting, pain,
- Are actors abdominal which often deign
- To act on behalf of the chest, spine or brain,
- Or general ills of which typhoid’s the main.

John Benjamin Murphy, 1857–1916, Professor of Surgery, Northwestern University, Chicago, IL, USA, described his sign in 1903. In 1896, he was the first person to successfully suture a severed femoral artery; in 1898, he was the first person to do thoracoplasty for pulmonary tuberculosis and pioneered bone grafting techniques. William Mayo said of him ‘the surgical genius of our generation’.

Or general ills of which typhoid’s the main.

**The Acute Abdomen in Rhyme**

Sir Vincent Zachary Cope, 1881–1975, surgeon, St Mary’s Hospital, London, UK. He was a poet who wrote a poetry book under a pseudonym ‘Zeta’ describing the acute abdomen: ‘The Acute Abdomen in Rhyme’. He described the differential diagnosis of acute appendicitis as:

- Distension, rigidity, vomiting, pain,
- Are actors abdominal which often deign
- To act on behalf of the chest, spine or brain,
- Or general ills of which typhoid’s the main.
Special features, according to position of the appendix

Retrocaecal

Rigidity is often absent, and even application of deep pressure may fail to elicit tenderness (silent appendix), the reason being that the caecum, distended with gas, prevents the pressure exerted by the hand from reaching the inflamed structure. However, deep tenderness is often present in the loin, and rigidity of the quadratus lumborum may be in evidence. Psoas spasm, due to the inflamed appendix being in contact with that muscle, may be sufficient to cause flexion of the hip joint. Hyperextension of the hip joint may induce abdominal pain when the degree of psoas spasm is insufficient to cause flexion of the hip.

Pelvic

Occasionally, early diarrhoea results from an inflamed appendix being in contact with the rectum. When the appendix lies entirely within the pelvis, there is usually complete absence of abdominal rigidity, and often tenderness over McBurney’s point is also lacking. In some instances, deep tenderness can be made out just above and to the right of the symphysis pubis. In either event, a rectal examination reveals tenderness in the rectovesical pouch or the pouch of Douglas, especially on the right side. Spasm of the psoas and obturator internus muscles may be present when the appendix is in this position. An inflamed appendix in contact with the bladder may cause frequency of micturition. This is more common in children.

Postileal

In this case, the inflamed appendix lies behind the terminal ileum. It presents the greatest difficulty in diagnosis because the pain may not shift, diarrhoea is a feature and marked retching may occur. Tenderness, if any, is ill defined, although it may be present immediately to the right of the umbilicus.

Special features, according to age

Infants

Appendicitis is relatively rare in infants under 36 months of age and, for obvious reasons, the patient is unable to give a history. Because of this, diagnosis is often delayed, and thus the incidence of perforation and postoperative morbidity is considerably higher than in older children. Diffuse peritonitis can develop rapidly because of the underdeveloped greater omentum, which is unable to give much assistance in localising the infection.

Children

It is rare to find a child with appendicitis who has not vomited. Children with appendicitis usually have complete aversion to food.

The elderly

Gangrene and perforation occur much more frequently in elderly patients. Elderly patients with lax abdominal walls or obesity may harbour a gangrenous appendix with little evidence of it, and the clinical picture may simulate subacute intestinal obstruction. These features, coupled with coincident medical conditions, produce a much higher mortality for acute appendicitis in the elderly.

The obese

Obesity can obscure and diminish all the local signs of acute appendicitis. Delay in diagnosis, coupled with the technical difficulty of operating in the obese, makes it wiser to consider operating through a midline abdominal incision. Laparoscopy is particularly useful in the obese as it may obviate the need for a large abdominal incision.

Pregnancy

Appendicitis is the most common extrauterine acute abdominal condition in pregnancy, with a frequency of 1:1500–2000 pregnancies. Diagnosis is complicated by delay in presentation as early non-specific symptoms are often attributed to the pregnancy. Obstetric teaching has been that the caecum and appendix are progressively pushed to the right upper quadrant of the abdomen as pregnancy develops during the second and third trimesters. However, pain in the right lower quadrant of the abdomen remains the cardinal feature of appendicitis in pregnancy. Fetal loss occurs in 3–5 per cent of cases, increasing to 20 per cent if perforation is found at operation.

Differential diagnosis

Although acute appendicitis is the most common abdominal surgical emergency, the diagnosis can be extremely difficult at times. There are a number of common conditions that it is wise to consider carefully and, if possible, exclude. The differential diagnosis differs in patients of different ages; in women, additional differential diagnoses are diseases of the female genital tract (Table 71.1).

Children

The diseases most commonly mistaken for acute appendicitis are acute gastroenteritis and mesenteric lymphadenitis. In mesenteric lymphadenitis, the pain is colicky in nature and cervical lymph nodes may be enlarged. It may be impossible to clinically distinguish Meckel’s diverticulitis from acute appendicitis. The pain is similar; however, signs may be central or left sided. Occasionally, there is a history of antecedent abdominal pain or intermittent lower gastrointestinal bleeding.

It is important to distinguish between acute appendicitis and intussusception. Appendicitis is uncommon before the age of two years, whereas the median age for intussusception is 18 months. A mass may be palpable in the right lower quadrant, and the preferred treatment of intussusception is reduction by careful barium enema.

Henoch–Schönlein purpura is often preceded by a sore throat or respiratory infection. Abdominal pain can be severe and can be confused with intussusception or appendicitis. There is nearly always an ecchymotic rash, typically affecting the extensor surfaces of the limbs and on the buttocks. The face is usually spared. The platelet count and bleeding time are within normal limits. Microscopic haematuria is common.

Lobar pneumonia and pleurisy, especially at the right base, may give rise to right-sided abdominal pain and mimic appendicitis. Abdominal tenderness is minimal, pyrexia is marked,

and chest examination may reveal a pleural friction rub or altered breath sounds on auscultation. A chest radiograph is diagnostic.

**Adults**

Terminal ileitis in its acute form may be indistinguishable from acute appendicitis unless a doughy mass of inflamed ileum can be felt. An antecedent history of abdominal cramping, weight loss and diarrhoea suggests regional ileitis rather than appendicitis. The ileitis may be non-specific, due to Crohn’s disease or *Yersinia* infection. *Yersinia enterocolitica* causes inflammation of the terminal ileum, appendix and caecum with mesenteric adenopathy. If suspected, serum antibody titres are diagnostic, and treatment with intravenous tetracycline is appropriate. If *Yersinia* infection is suspected at operation, a mesenteric lymph node should be excised and divided, with half submitted for microbiological culture (including tuberculosis) and half for histological examination.

Ureteric colic does not commonly cause diagnostic difficulty, as the character and radiation of pain differs from that of appendicitis. Urinalysis should always be performed, and the presence of red cells should prompt a supine abdominal radiograph. Renal ultrasound or intravenous urogram is diagnostic.

Right-sided acute pyelonephritis is accompanied and often preceded by increased frequency of micturition. It may cause difficulty in diagnosis, especially in women. The leading features are rigors confined to the loin, fever (temperature 39°C) and possibly rigors and pyuria.

In perforated peptic ulcer, the duodenal contents pass along the paracolic gutter to the right iliac fossa. As a rule, there is a history of dyspepsia and a very sudden onset of pain that starts in the epigastrium and passes down the right paracolic gutter. In appendicitis, the pain starts classically in the umbilical region. Rigidity and tenderness in the right iliac fossa are present in both conditions but, in perforated duodenal ulcer, the rigidity is usually greater in the right hypochondrium. An erect chest radiograph will show gas under the diaphragm in 70 per cent of patients. An abdominal computed tomography (CT) examination is valuable when there is diagnostic difficulty.

Testicular torsion in a teenage or young adult male is easily missed. Pain can be referred to the right iliac fossa, and shyness on the part of the patient may lead the unwary to suspect appendicitis unless the scrotum is examined in all cases.

Acute pancreatitis should be considered in the differential diagnosis of all adults suspected of having acute appendicitis and, when appropriate, should be excluded by serum or urinary amylase measurement.

Rectus sheath haematoma is a relatively rare but easily missed differential diagnosis. It usually presents with acute pain and localised tenderness in the right iliac fossa, often after an episode of strenuous physical exercise. Localised pain without gastrointestinal upset is the rule. Occasionally, in an elderly patient, particularly one taking anticoagulant therapy, a rectus sheath haematoma may present as a mass and tenderness in the right iliac fossa after minor trauma.

**Adult female**

It is in women of childbearing age that pelvic disease most often mimics acute appendicitis. A careful gynaecological history should be taken in all women with suspected appendicitis, concentrating on menstrual cycle, vaginal discharge and possible pregnancy (see also Chapter 80). The most common diagnostic mimics are pelvic inflammatory disease (PID), Mittelschmerz, torsion or haemorrhage of an ovarian cyst and ectopic pregnancy.

**Pelvic inflammatory disease**

PID comprises a spectrum of diseases that include salpingitis, endometritis and tubo-ovarian sepsis. The incidence of these conditions is increasing and the diagnosis should be considered in every young adult female. Typically, the pain is lower than in appendicitis and is bilateral. A history of vaginal discharge, dysmenorrhoea and burning pain on micturition is a helpful differential diagnostic point. The physical findings include adnexal and cervical tenderness on vaginal examination. When suspected, a high vaginal swab should be taken for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* culture, and the opinion of a gynaecologist should be obtained. Treatment is usually a combination of ofloxacin and metronidazole for 14 days. Transvaginal ultrasound can be particularly helpful in establishing the diagnosis. When serious diagnostic uncertainty persists, diagnostic laparoscopy should be undertaken.

**Mittelschmerz**

Midcycle rupture of a follicular cyst with bleeding produces lower abdominal and pelvic pain, typically midcycle. Systemic upset is rare, a pregnancy test is negative, and symptoms usu-

ally subside within hours. Occasionally, diagnostic laparoscopy is required. Retrograde menstruation may cause similar symptoms.

**Torsion/haemorrhage of an ovarian cyst**
This can prove a difficult differential diagnosis. When suspected, pelvic ultrasound and a gynaecological opinion should be sought. If encountered at operation in women of childbearing years, untwisting of the involved adnexa and ovarian cystectomy should be performed, if necessary. Documented visualisation of the contralateral ovary is an essential medicolegal precaution prior to oophorectomy for any reason.

**Ectopic pregnancy**
It is unlikely that a ruptured ectopic pregnancy, with its well-defined signs of haemoperitoneum, will be mistaken for acute appendicitis, but the same cannot be said for a right-sided tubal abortion, or still more for a right-sided unruptured tubal pregnancy. In the latter, the signs are very similar to those of acute appendicitis, except that the pain commences on the right side and stays there. The pain is severe and continues unabated until operation. Usually, there is a history of a missed menstrual period, and a urinary pregnancy test may be positive. Severe pain is felt when the cervix is moved on vaginal examination. Signs of intraperitoneal bleeding usually become apparent, and the patient should be questioned specifically regarding referred pain in the shoulder. Pelvic ultrasonography should be carried out in all cases in which an ectopic pregnancy is a possible diagnosis.

**Elderly**

**Diverticulitis**
In some patients with a long sigmoid loop, the colon lies to the right of the midline, and it may be impossible to differentiate between diverticulitis and appendicitis. Abdominal CT scanning is particularly useful in this setting and should be considered in the management of all patients over the age of 60 years. A trial of conservative management with intravenous fluids and antibiotics is often appropriate, with a low threshold for laparoscopy or exploratory laparotomy in the face of deterioration or lack of clinical response. Right-sided diverticulitis is unusual and may be clinically indistinguishable from appendicitis. Abdominal CT scanning is particularly useful in making the distinction. As with left-sided diverticulitis, treatment should be conservative with intravenous antibiotics with recourse to laparoscopy or laparotomy in the face of deterioration.

**Intestinal obstruction**
The diagnosis of intestinal obstruction is usually clear; the subtlety lies in recognising acute appendicitis as the occasional cause in the elderly. As with diverticulitis, intravenous fluids, antibiotics and nasogastric decompression should be instigated, with early resort to laparotomy.

**Carcinoma of the caecum**
When obstructed or locally perforated, carcinoma of the caecum may mimic or cause obstructive appendicitis in adults. A history of antecedent discomfort, altered bowel habit or unexplained anaemia should raise suspicion. A mass may be palpable (see below under Carcinoid tumour) and an abdominal CT scan diagnostic.

**Rare differential diagnoses**
Preherpetic pain of the right 10th and 11th dorsal nerves is localised over the same area as that of appendicitis. It does not shift and is associated with marked hyperaesthesia. There is no intestinal upset or rigidity. The herpetic eruption may be delayed for 3–8 hours.

**Tabetic crises** are now rare. Severe abdominal pain and vomiting usher in the crisis. Other signs of tabes confirm the diagnosis.

**Spinal conditions** are sometimes associated with acute abdominal pain especially in children and the elderly. These may include tuberculosis of the spine, metastatic carcinoma, osteoporotic vertebral collapse and multiple myeloma. The pain is due to compression of nerve roots and may be aggravated by movement. There is rigidity of the lumbar spine and intestinal symptoms are absent.

The abdominal crises of porphyria and diabetes mellitus need to be remembered. A urinalysis should be undertaken in every abdominal emergency. In cyclical vomiting of infants or young children, there is a history of previous similar attacks and abdominal rigidity is absent. Acetone is found in the urine but is not diagnostic as it may accompany starvation.

**Typhlitis** or leukaeic ileocaecal syndrome is a rare but potentially fatal enterocolitis occurring in immunosuppressed patients. Gram-negative or clostridial septicemia (especially Clostridium septicum) can be rapidly progressive. Treatment is with appropriate antibiotics and haematopoietic factors. Surgical intervention is rarely indicated.

**Investigation**
The diagnosis of acute appendicitis is essentially clinical; however, a decision to operate based on clinical suspicion alone can lead to the removal of a normal appendix in 15–30 per cent of cases. The premise that it is better to remove a normal appendix than to delay diagnosis does not stand up to close scrutiny, particularly in the elderly. A number of clinical and laboratory-based scoring systems have been devised to assist diagnosis. The most widely used is the Alvarado score (Table 71.2). A score of 7 or more is strongly predictive of acute appendicitis.

In patients with an equivocal score (5–6), abdominal ultrasound or contrast-enhanced CT examination further reduces the rate of negative appendicectomy. Abdominal ultrasound examination is more useful in children and thin adults, particularly if gynaecological pathology is suspected, with a diagnostic accuracy in excess of 90 per cent (Figure 71.10). Contrast-enhanced CT scan (Figure 71.11) is most useful in patients in whom there is diagnostic uncertainty, particularly older patients, in whom acute diverticulitis, intestinal obstruction and neoplasm are likely differential diagnoses. Selective use of CT scanning may be cost-effective by reducing both the negative appendicectomy rate and the length of hospital stay (Summary box 71.5).

**Treatment**
The traditional treatment for acute appendicitis is appendicectomy. While this remains standard teaching, there is an

---

Alfredo Alvarado, trained in medicine in Bogota, Columbia, contemporary, surgeon, Plantation, FL, USA, described his scoring system in 1986.
emerging body of literature to support a trial of conservative management in those thought not to have obstructive appendicitis. Treatment is bowel rest and intravenous antibiotics, usually metronidazole and third-generation cephalosporin. The available data indicate successful outcomes in 80–90 per cent of patients, however there is an approximately 15 per cent recurrence rate within one year. This approach should be considered in patients with high operative risk (multiple comorbidities). As with conservative treatment of an appendix mass, patients over the age of 40 should be followed up to ensure there is no underlying malignancy (see below under Management of an appendix mass).

With regard to appendicectomy, there is a perception that emergency, often out of hours, operation is essential to prevent the increased morbidity and mortality of peritonitis. While there should be no unnecessary delay, all patients, particularly those most at risk of serious morbidity, benefit by a short period of intensive preoperative preparation. Intravenous fluids, sufficient to establish adequate urine output (catheterisation is needed only in the very ill), and appropriate antibiotics should be given. There is ample evidence that in the absence of purulent peritonitis, a single preoperative dose of antibiotics reduces the incidence of postoperative wound infection. When peritonitis is suspected, therapeutic intravenous antibiotics to cover Gram-negative bacilli, as well as anaerobic cocci, should be given. Hyperpyrexia in children should be treated with salicylates in addition to antibiotics and intravenous fluids. With appropriate use of intravenous fluids and parenteral antibiotics, a policy of deferring appendicectomy after midnight to the first case on the following morning does not increase morbidity. However, when acute obstructive appendicitis is recognised, operation should not be deferred longer than it takes to optimise the patient’s condition.

### Appendicectomy

Claudius Amyand successfully removed an acutely inflamed appendix from the hernial sac of a boy in 1736. The first surgeon to perform deliberate appendicectomy for acute appendicitis was Lawson Tait in May 1880. The patient recovered; however, the case was not reported until 1890. Meanwhile, Thomas Morton was the first to diagnose appendicitis, drain the abscess and remove the appendix with recovery, publishing his findings in 1887.

**Summary box 71.5**

**Preoperative investigations in appendicitis**

- **Routine**
  - Full blood count
  - Urinalysis
- **Selective**
  - Pregnancy test
  - Urea and electrolytes
  - Supine abdominal radiograph
  - Ultrasound of the abdomen/pelvis
  - Contrast-enhanced abdomen and pelvic computed tomography scan

**Figure 71.10** Abdominal ultrasound examination showing features of acute appendicitis, distended oedematous appendix (open arrows), longitudinal scan (left) and transverse scan (right). A faecolith is seen (closed arrow) (courtesy of Dr M Behan, FRCR, Dublin, Ireland).

**Figure 71.11** Abdominal contrast-enhanced computed tomography scan showing a faecolith (open arrow) at the base of a distended (>0.6 cm) appendix with intramural gas (white arrows) (courtesy of Professor H Fenlon, FRCR, Dublin, Ireland).
Appendicectomy should be performed under general anaesthetic with the patient supine on the operating table. When a laparoscopic technique is to be used, the bladder must be empty (ensure that the patient has voided before leaving the ward). Prior to preparing the entire abdomen with an appropriate antiseptic solution, the right iliac fossa should be palpated for a mass. If a mass is felt, it may, on occasion, be preferable to adopt a conservative approach (see below under Management of an appendix mass). Draping of the abdomen is in accordance with the planned operative technique, taking account of any requirement to extend the incision or convert a laparoscopic technique to an open operation.

**Conventional appendicectomy**

When the preoperative diagnosis is considered reasonably certain, the incision that is widely used for appendicectomy is the so-called gridiron incision (gridiron: a frame of cross-beams to support a ship during repairs). The gridiron incision (described first by McArthur) is made at right angles to a line joining the anterior superior iliac spine to the umbilicus, its centre being along the line at McBurney’s point (Figure 71.12). If better access is required, it is possible to convert the gridiron to a Rutherford Morison incision (see below) by cutting the internal oblique and transversus muscles in the line of the incision.

In recent years, a transverse skin crease (Lanz) incision has become more popular, as the exposure is better and extension, when needed, is easier. The incision, appropriate in length to the size and obesity of the patient, is made approximately 2 cm below the umbilicus centred on the midclavicular–midinguinal line (Figure 71.13). When necessary, the incision may be extended medially, with retraction or suitable division of the rectus abdominis muscle.

When the diagnosis is in doubt, particularly in the presence of intestinal obstruction, a lower midline abdominal incision is to be preferred over a right lower paramedian incision. The latter, although widely practised in the past, is difficult to extend, more difficult to close and provides poorer access to the pelvis and peritoneal cavity.

Rutherford Morison’s incision is useful if the appendix is para- or retrocaecal and fixed. It is essentially an oblique muscle-cutting incision with its lower end over McBurney’s point and extending obliquely upwards and laterally as necessary. All layers are divided in the line of the incision.

**Removal of the appendix**

The caecum is identified by the presence of taeniae coli and, using a finger or a swab, the caecum is withdrawn. A turgid appendix may be felt at the base of the caecum. Inflammatory adhesions must be gently broken with a finger, which is then hooked around the appendix to deliver it into the wound. The appendix is conveniently controlled using a Babcock or Lane’s forceps applied in such a way as to encircle the appendix and yet not damage it. The base of the mesoappendix is clamped in artery forceps, divided and ligated (Figure 71.14a). When the mesoappendix is broad, the procedure must be repeated with a second or, rarely, a third artery forceps. The appendix, now completely freed, is crushed near its junction with the caecum in artery forceps, which is removed and reapplied just distal to the crushed portion. An absorbable 2/0 ligature is tied around the crushed portion close to the caecum. The appendix is amputated between the artery forceps and the ligature (Figure 71.14b). An absorbable 2/0 or 3/0 purse-string or ‘Z’ suture may then be inserted into the caecum about 1.25 cm from the base (Figure 71.14c). The stitch should pass through the muscle.
coat, picking up the taeniae coli. The stump of the appendix is invaginated (Figure 71.14d) while the purse-string or 'Z' suture is tied, thus burying the appendix stump. Many surgeons believe invagination of the appendiceal stump is unnecessary.

Methods to be adopted in special circumstances
When the caecal wall is oedematous, the purse-string suture is in danger of cutting out. If the oedema is of limited extent, this can be overcome by inserting the purse-string suture into more healthy caecal wall at a greater distance from the base of the appendix. Occasions may arise when, because of the extensive oedema of the caecal wall, it is better not to attempt invagination.

When the base of the appendix is inflamed, it should not be crushed, but ligated close to the caecal wall just tightly enough to occlude the lumen, after which the appendix is amputated and the stump invaginated. Should the base of the appendix be gangrenous, neither crushing nor ligation should be attempted. Two stitches are placed through the caecal wall close to the base of the gangrenous appendix, which is amputated flush with the caecal wall, after which these stitches are tied. Further closure is effected by means of a second layer of interrupted seromuscular sutures.

Retrograde appendicectomy
When the appendix is retrocaecal and adherent, it is an advantage to divide the base between artery forceps. The appendical vessels are then ligated, the stump ligated and invaginated, and gentle traction on the caecum will enable the surgeon to deliver the body of the appendix, which is then removed from base to tip. Occasionally, this manoeuvre requires division of the lateral peritoneal attachments of the caecum.

Laparoscopic appendicectomy
The most valuable aspect of laparoscopy in the management of suspected appendicitis is as a diagnostic tool, particularly in women of child-bearing age. The placement of operating ports may vary according to operator preference and previous abdominal scars. The operator stands to the patient’s left and faces a video monitor placed at the patient’s right foot (Figure 71.15). A moderate Trendelenburg tilt of the operating table assists delivery of loops of small bowel from the pelvis. The appendix is found in the conventional manner by identification of the caecal taeniae and is controlled using a laparoscopic tissue-holding forceps. By elevating the appendix, the mesoappendix is displayed (Figure 71.16a). A dissecting forceps is used to create a window in the mesoappendix to allow the appendicular vessels to be coagulated or ligated using a clip applicator. The appendix, free of its mesentery, can be ligated at its base with an absorbable loop ligature (Figure 71.16b), divided (Figure 71.16c) and removed through one of the operating ports. It is not usual to invert the stump of the appendix (Figure 71.16d). A single absorbable suture is used to close the linea alba at the
The small skin incisions may be closed with subcuticular sutures.

Patients who undergo laparoscopic appendicectomy are likely to have less postoperative pain and to be discharged from hospital and return to activities of daily living sooner than those who have undergone open appendicectomy. While the incidence of postoperative wound infection is lower after the laparoscopic technique, the incidence of postoperative intra-abdominal sepsis may be higher in patients operated on for gangrenous or perforated appendicitis. There may be an advantage for laparoscopic over open appendicectomy in obese patients and early pregnancy. At present, there seems little, if any, benefit from single incision laparoscopic surgery (SILS) for acute appendicitis.

Problems encountered during appendicectomy
• A normal appendix is found. This demands careful exclusion of other possible diagnoses, particularly terminal ileitis, Meckel's diverticulitis and tubal or ovarian causes in women. It is usual to remove the appendix to avoid future diagnostic difficulties, even though the appendix umbilicus, and the small skin incisions may be closed with subcuticular sutures.

is macroscopically normal, particularly if a skin crease or gridiron incision has been made. A case can be made for preserving the macroscopically normal appendix seen at diagnostic laparoscopy, although approximately one-quarter of seemingly normal appendices show microscopic evidence of inflammation.

- **The appendix cannot be found.** The caecum should be mobilised, and the taeniae coli should be traced to their confluence on the caecum before the diagnosis of ‘absent appendix’ is made.
- **An appendicular tumour is found.** Small tumours (under 2.0 cm in diameter) can be removed by appendicectomy; larger tumours should be treated by a right hemicolectomy (see below).
- **An appendix abscess is found and the appendix cannot be removed easily.** This eventuality is rare in the era of modern diagnostic imaging. Percutaneous drainage of the abscess and intravenous antibiotic treatment is to be preferred. If found at operation, the abscess should be drained and intravenous antibiotics administered. Very rarely in the face of a frankly necrotic appendix, a caecelectomy or partial right hemicolecctiony is required. (The first recorded operation for an appendix abscess was by Henry Hancock of Charing Cross Hospital, London, in 1848.)

**Appendicitis complicating Crohn’s disease**

Occasionally, a patient undergoing surgery for acute appendicitis is found to have concomitant Crohn’s disease of the ileocaecal region. Providing that the caecal wall is healthy at the base of the appendix, appendicectomy can be performed without increasing the risk of an enterocutaneous fistula. Rarely, the appendix is involved with the Crohn’s disease. In this situation, a conservative approach may be warranted, and a trial of intravenous corticosteroids and systemic antibiotics can be used to resolve the acute inflammatory process.

**Appendix abscess**

Failure of resolution of an appendix mass or continued spiking pyrexia usually indicates that there is pus within the phlegmonous appendix mass. Ultrasound or abdominal CT scan may identify an area suitable for the insertion of a percutaneous drain. Rarely, this is unsuccessful and laparotomy through a midline incision is indicated.

**Pelvic abscess**

Pelvic abscess formation is an occasional complication of appendicitis and can occur irrespective of the position of the appendix within the peritoneal cavity. The most common presentation is a spiking pyrexia several days after appendicitis; indeed, the patient may already have been discharged from hospital. Pelvic pressure or discomfort associated with loose stool or tenesmus is common. Rectal examination reveals a boggy mass in the pelvis, anterior to the rectum, at the level of the peritoneal reflection (Figure 71.17). Pelvic ultrasound or CT scan will confirm. Traditionally, treatment has been through transrectal drainage under general anaesthetic, however increasing availability of radiologically guided percutaneous drainage has reduced the need considerably.

---

**Summary box 71.6**

Criteria for stopping conservative treatment of an appendix mass

- A rising pulse rate
- Increasing or spreading abdominal pain
- Increasing size of the mass

Careful recording of the patient’s condition and the extent of the mass should be made and the abdomen regularly re-examined. It is helpful to mark the limits of the mass on the abdominal wall using a skin pencil. A contrast-enhanced CT examination of the abdomen should be performed and antibiotic therapy instigated. An abscess, if present, should be drained radiologically. Temperature and pulse rate should be recorded 4-hourly and a fluid balance record maintained. Clinical deterioration or evidence of peritonitis is an indication for early surgery.
laparotomy. Clinical improvement is usually evident within 24–48 hours. Failure of the mass to resolve should raise suspicion of a carcinoma or Crohn’s disease. Using this regimen, approximately 90 per cent of cases resolve without incident. The great majority of patients will not develop recurrence, and it is no longer considered necessary to remove the appendix after an interval of 6–8 weeks. Patients over the age of 40 should have colonoscopy and follow-up imaging to ensure resolution as a small minority (less than 5 per cent) may have an underlying appendicular or colonic malignancy.

**Postoperative complications**

Postoperative complications following appendicectomy are relatively uncommon and reflect the degree of peritonitis that was present at the time of operation and intercurrent diseases that may predispose to complications (Summary box 71.7).

### Summary box 71.7

**Checklist for unwell patient following appendicectomy**

- Examine the wound and abdomen for an abscess
- Consider a pelvic abscess and perform a rectal examination
- Examine the lungs – pneumonitis or collapse
- Examine the legs – consider venous thrombosis
- Examine the conjunctivae for an icteric tinge and the liver for enlargement, and enquire whether the patient has had rigors (pyelonephritis)
- Examine the urine for organisms (pyelonephritis)
- Suspect subphrenic abscess

**Wound infection**

Wound infection is the most common postoperative complication, occurring in 5–10 per cent of all patients. This usually presents with pain and erythema of the wound on the 4th or 5th postoperative day, often soon after hospital discharge. Treatment is by wound drainage and antibiotics when required. The organisms responsible are usually a mixture of Gram-negative bacilli and anaerobic bacteria, predominantly Bacteroides species and anaerobic streptococci.

**Intra-abdominal abscess**

Approximately 8 per cent of patients following appendicectomy will develop a postoperative intra-abdominal abscess. In an era of hospital discharge 24 to 48 hours following appendicectomy, patients should be advised prior to discharge that a spiking fever, malaise and anorexia developing 5–7 days after operation is suggestive of an intraperitoneal collection and that urgent medical advice should be obtained. Interloop, paracolic, pelvic and subphrenic sites should be considered. Abdominal ultrasonography and CT scanning greatly facilitate diagnosis and allow percutaneous drainage. Laparotomy should be considered in patients suspected of having intra-abdominal sepsis, but in whom imaging fails to show a collection, particularly those with continuing ileus.

**Ileus**

A period of adynamic ileus is to be expected after appendicectomy, and this may last a number of days following removal of a gangrenous appendix. Ileus persisting for more than 4 or 5 days, particularly in the presence of a fever, is indicative of continuing intra-abdominal sepsis and should prompt further investigation (see above). Rarely, early during postoperative recovery, a Richter’s type of hernia may occur at the site of a laparoscopic port insertion and may be confused with a postoperative ileus. A CT scan is usually definitive.

**Respiratory**

In the absence of concurrent pulmonary disease, respiratory complications are rare following appendicectomy. Adequate postoperative analgesia and physiotherapy, when appropriate, reduce the incidence.

**Venous thrombosis and embolism**

These conditions are rare after appendicectomy, except in the elderly and in women taking the oral contraceptive pill. Appropriate prophylactic measures should be taken in such cases.

**Portal pyaemia (pyelonephritis)**

This is a rare but very serious complication of gangrenous appendicitis associated with high fever, rigors and jaundice. It is caused by sepsicaemia in the portal venous system and leads to the development of intrahepatic abscesses (often multiple). Treatment is with systemic antibiotics and percutaneous drainage of hepatic abscesses as appropriate. A screen for underlying thrombophilia should be considered.

**Faecal fistula**

Leakage from the appendicular stump occurs rarely, but may follow if the encircling stitch has been put in too deeply or if the caecal wall was involved by oedema or inflammation. Occasionally, a fistula may result following appendicectomy in Crohn’s disease. Conservative management with low-residue enteral nutrition will usually result in closure.

**Adhesive intestinal obstruction**

This is the most common late complication of appendicectomy. At operation, a single band adhesion is often found to be responsible. Occasionally, chronic pain in the right iliac fossa is attributed to adhesion formation after appendicectomy. In such cases, laparoscopy is of value in confirming the presence of adhesions and allowing division.

**Recurrent acute appendicitis**

Appendicitis is notoriously recurrent. It is not uncommon for patients to attribute such attacks to ‘biliousness’ or dyspepsia. The attacks vary in intensity and may occur every few months, and the majority of cases ultimately culminate in severe acute appendicitis. If a careful history is taken from patients with acute appendicitis, many remember having had milder but similar attacks of pain. The appendix in these cases shows fibrosis indicative of previous inflammation (Figure 71.18). Chronic appendicitis, per se, does not exist; however, there is evidence of altered neuroimmune function in the myenteric nerves of patients with so-called recurrent appendicitis (Büchler).
Neoplasms of the appendix

Carcinoid tumours

Carcinoid tumours (synonym: argentaffinoma) arise in argentaffin tissue (Kulchitsky cells of the crypts of Lieberkühn) and are most common in the vermiform appendix. Carcinoid tumour is found once in every 300–400 appendices subjected to histological examination and is ten times more common than any other neoplasm of the appendix. In many instances, the appendix had been removed because of symptoms of subacute or recurrent appendicitis. The tumour can occur in any part of the appendix, but it is frequently found in the distal third. The neoplasm feels moderately hard and, on sectioning the appendix, it can be seen as a yellow tumour between the intact mucosa and the peritoneum. Microscopically, the tumour cells are small, arranged in small nests within the muscle and have a characteristic pattern using immunohistochemical stain for chromogranin B (Figure 71.19). Unlike carcinoid tumours arising in other parts of the intestinal tract, carcinoid tumour of the appendix rarely gives rise to metastases. Appendicectomy has been shown to be sufficient treatment, unless the caecal wall is involved, the tumour is 2 cm or more in size or involved lymph nodes are found, when right hemicolecctomy is indicated.

Other appendiceal tumours

Goblet cell carcinoid tumour is an unusual variant, which exhibits a combination of endocrine and glandular differentiation. It has a more aggressive natural history and right hemicolecctomy is indicated if the tumour is 2 cm or more in size, has greater than two mitoses per high power field, involved margins or lymphovascular invasion.

Primary adenocarcinoma of the appendix is extremely rare. It is usually of the colonic type and should be treated by right hemicolecctomy (as a second-stage procedure if the condition is not recognised at the first operation).

Mucinous cystadenoma

A mucin-secreting adenoma of the appendix may rupture into the peritoneal cavity (Figure 71.20), seeding it with mucus-secreting cells. Presentation is often delayed until the patient has gross abdominal distension as a result of pseudomyxoma peritonei, which may mimic ascites (Figure 71.21). Treatment consists of radical resection of all involved parietal peritoneal surfaces and aggressive intraperitoneal chemotherapy (Sugarbaker). When diagnosed, patients should be referred to specialist centres that have the requisite facilities and experience to undertake the prolonged and complex surgery involved.

ABDOMINAL

THE VERMIFORM APPENDIX

FURTHER READING

Figure 71.21 Pseudomyxoma peritonei. Operative photograph illustrating the extensive peritoneal seeding by mucin-producing cells (courtesy Mr Brendan Moran, FRCSI, FRCS, and reproduced with permission Basingstoke and North Hampshire NHS Foundation Trust, UK).

The rectum begins where the taenia coli of the sigmoid colon join to form a continuous outer longitudinal muscle layer at the level of the sacral promontory. The rectum follows the curve of the sacrum, and ends at the anorectal junction. The puborectalis muscle encircles the posterior and lateral aspects of the junction, creating the anorectal angle (normally 120°). The rectum has three lateral curvatures: the upper and lower are convex to the right, and the middle is convex to the left. On the luminal aspect, these three curves are marked by semicircular folds (Houston’s valves) (Figure 72.1).

The adult rectum is approximately 12–18 cm in length and is conventionally divided into three equal parts: the upper third, which is mobile and has a peritoneal covering anteriorly and laterally; the middle third, where the peritoneum covers only the anterior and part of the lateral surfaces; and the lowest third, which lies deep in the pelvis surrounded by fatty mesorectum and is separated from adjacent structures by fascial layers.

The lower third of the rectum is separated by a fascial condensation (Denonvilliers’ fascia) from the prostate/vagina in front, and behind by another fascial layer (Waldeyer’s fascia) from the coccyx and lower two sacral vertebrae (Table 72.1). These fascial layers are surgically important as they are a barrier to malignant invasion (Summary box 72.1).

Summary box 72.1

Anatomy of the rectum
- The rectum measures approximately 15 cm in length
- It is divided into lower, middle and upper thirds
- The blood supply consists of superior, middle and inferior rectal vessels
- Although the lymphatic drainage follows the blood supply, the principal route is upwards along the superior rectal vessels to the para-aortic nodes

Blood supply
The superior rectal artery is the direct continuation of the inferior mesenteric artery and is the main arterial supply of the rectum. The arteries and their accompanying lymphatics lie within the loose fatty tissue of the mesorectum, surrounded by a sheath of connective tissue (the mesorectal fascia).

The middle rectal artery arises on each side from the internal iliac artery (Figure 72.2) and passes to the rectum in the lateral ligaments. It is usually small (and often only present on one side) and breaks up into several terminal branches.

The inferior rectal artery arises on each side from the internal pudendal artery as it enters Alcock’s canal. It hugs the inferior surface of the levator ani muscle as it crosses the roof of the ischiorectal fossa to enter the anal muscles (Figure 72.2).

Venous drainage
The superior haemorrhoidal veins draining the upper half of the anal canal above the dentate line pass upwards to become the rectal veins: these unite to form the superior rectal vein, which later becomes the inferior mesenteric vein. This forms part of the portal venous system and ultimately drains into the splenic vein. Middle rectal veins exist but are small, unimportant channels unless the normal paths are blocked.

Lymphatic drainage
The lymphatics of the mucosal lining of the rectum communicate freely with those of the muscular layers. The usual drainage flow is upwards, and only to a limited extent laterally and downwards. For this reason, surgical clearance of malignant disease concentrates mainly on achieving wide resection of proximal lymph nodes. However, if the usual upwards routes are blocked (for example, by carcinoma), flow can reverse, and it is then possible to find metastatic lymph nodes on the side walls of the pelvis (along the middle rectal vessels) or even in the inguinal region (along the inferior rectal artery).

CLINICAL FEATURES OF RECTAL DISEASE

Symptoms
Rectal diseases are common and serious and can occur at any age. The symptoms of many of them overlap. In general, the inflammations affect younger age groups, while the tumours occur in the middle-aged and elderly. The common symptoms of rectal disease are shown in Summary box 72.2.

Summary box 72.2

Main symptoms of rectal disease
- Bleeding per rectum
- Altered bowel habit
- Mucus discharge
- Tenesmus
- Prolapse

Bleeding
This is often bright red in colour but may be darker, and should be carefully investigated at any age.

Altered bowel habit
Early-morning stool frequency (‘spurious diarrhoea’) is a symptom of rectal carcinoma, while blood-stained frequent loose stools characterise the inflammatory diseases.

Discharge
Mucus and pus are associated with rectal pathology.

Tenesmus
Often described by the patient as ‘I feel I want to go, but nothing happens’, this is normally an ominous symptom of rectal cancer, but can occur with any rectal pathology.

Prolapse
This usually indicates either mucosal or full-thickness rectal wall descent.

Loss of weight
This usually indicates serious or advanced disease, e.g. hepatic metastases.
**Signs**

Because the rectum is accessible via the anus, these can be elicited by systematic examination. The patient is either positioned in the left lateral (Sims) position or examined in the knee–elbow position (Figure 72.3).

**Inspection**

Visual examination of the anus precedes rectal examination to exclude the presence of anal disease, e.g. fissure or fistula.

**Digital examination**

The index finger used with gentleness and precision remains a valuable test for rectal disease (Figure 72.4). Tumours in the lower and middle thirds of the rectum can be felt and assessed; by asking the patient to strain, even some tumours in the upper third can be ‘tipped’ with the finger. After it is removed, the finger should be examined for tell-tale traces of mucus, pus or blood. It is always useful to note the normal, as well as the abnormal findings on digital examination, e.g. the prostate in the male. Digital findings can be recorded as intraluminal (e.g. blood, pus), intramural (e.g. tumours, granular areas, strictures) or extramural (e.g. enlarged prostate, uterine fibroids).

**Proctoscopy**

This procedure can be used to inspect the anus, anorectal junction and lower rectum (up to 10 cm) (Figure 72.5). Biopsy can be performed of any suspicious areas.

**Sigmoidoscopy**

In the past, the sigmoidoscope was a rigid stainless steel instrument of variable diameter and normally 25 cm in length (Figure 72.5). This has in the main been replaced by a disposable plastic instrument. The rectum must be empty for proper inspection with a sigmoidoscope. Gentleness and skill are required for its use, and perforations can occur if care is not taken.

**Flexible sigmoidoscope**

The ‘flexiscope’ can be used to supplement or replace rigid sigmoidoscopy (Figure 72.6). It requires skill and experience, and the lower bowel should be cleaned out with preliminary enemas. In addition to the rectum, the whole sigmoid colon is within visual reach of this instrument (Summary box 72.3).

---

**Summary box 72.3**

**Examination of the rectum**

- Visual inspection of the perineum
- Digital examination
- Proctoscopy
- Sigmoidoscopy – rigid or flexible

---

**INJURIES**

The rectum or anal canal may be injured in a number of ways, all uncommon:

---

*James Marion Sims*, 1813–1883, gynaecological surgeon, the State Hospital for Women, New York, NY, USA, introduced this position to give access to the anterior vaginal wall during operations for the closure of vaginovestibular fistulae.

*Charles Victor Mann*, formerly surgeon, St Mark’s Hospital and Royal London Hospital, London, UK.
by falling in a sitting posture onto a pointed object: the upturned leg of a chair, handle of a broom, floor-mop, pitchfork or a broken shooting stick have all resulted in rectal impalement;
• by penetrating injury (including gunshots) to the buttocks;
• by sexual assault or sexual activity involving anal penetration;
• by the fetal head during childbirth, especially forceps-assisted.

Diagnosis
The anus should be inspected and the abdomen palpated. If rigidity or tenderness is present, early laparotomy or laparoscopy is indicated. A water-soluble contrast enema or computed tomography (CT) scan with rectal contrast is useful to identify perforation. Prior to the operation, a urethral catheter is passed, but if there is any possibility of urethral injury (suggested by difficulty passing urine, haematuria or high prostate on digital examination), a urethrogram should be performed first (see Chapters 76 and 78).

Treatment
If perforation is suspected, the rectum is examined under general anaesthetic with a finger and a sigmoidoscope, particular attention being directed to the anterior wall. If penetrating injury is confirmed, laparotomy or laparoscopy is then performed. If an intraperitoneal rupture of the rectum is found, the perforation is closed with sutures. A defunctioning colostomy is usually required, constructed in the left iliac fossa. If the rectal injury is below the peritoneal reflection, wide drainage from below is indicated, with rectal washout and a defunctioning colostomy. If the defect in the rectum is very large, resection may have to be contemplated, usually in the form of a Hartmann’s procedure. Care must be taken to preserve sphincter function during debridement of the perineal wounds. Antibiotic cover must be provided against both aerobic and anaerobic organisms.

FOREIGN BODIES IN THE RECTUM
The variety of foreign bodies that have found their way into the rectum is hardly less remarkable than the ingenuity displayed in their removal (Figure 72.7). A turnip has been delivered per anum by the use of obstetric forceps. A large soft rubber sex toy has been withdrawn by inserting a myomectomy screw into its lower end. A tumbler, mouth open downwards, has been extracted by filling the interior with a wet plaster of Paris bandage, leaving the end of the bandage protruding and allowing the plaster to set.

If insurmountable difficulty is experienced in grasping any foreign body in the rectum, a laparotomy is usually necessary, which allows the object to be pushed from above into the assistant’s fingers in the rectum. If there is considerable laceration of the mucosa, a temporary colostomy is advisable (Summary box 72.4).
Injuries to the rectum are serious and invariably require surgery

- A temporary colostomy is often necessary
- There is a serious risk of associated necrotising fasciitis, and broad-spectrum antibiotics are mandatory
- There may be associated bladder or urethral damage

Summary box 72.5

Mucosal prolapse

The mucous membrane and submucosa of the rectum protrude outside the anus for approximately 1–4 cm. When the prolapsed mucosa is palpated between the finger and thumb, it is evident that it is composed of no more than a double layer of mucous membrane (see below under Full-thickness prolapse) (Summary box 72.5).

PROLAPSE

Mucosal prolapse
### Summary box 72.5

**Rectal prolapse**
- It may be mucosal or full thickness
- If full thickness, the whole wall of the rectum is included
- It commences as a rectal intussusception
- In children, the prolapse is usually mucosal and should be treated conservatively
- In the adult, the prolapse is often full thickness and is frequently associated with incontinence
- Surgery is necessary for full-thickness rectal prolapse
- The operation is performed either via the perineum or via the abdomen

### In infants

The direct downward course of the rectum, due to the as-yet undeveloped sacral curve (Figure 72.8), predisposes to this condition, as does the reduced resting anal tone, which offers diminished support to the mucosal lining of the anal canal.

### In children

Mucosal prolapse often commences after an attack of diarrhoea, or from loss of weight and consequent loss of fat in the ischiorectal fossae. It may also be associated with cystic fibrosis, neurological causes and maldevelopment of the pelvis.

### In adults

The condition in adults is often associated with third-degree haemorrhoids. In the female, a torn perineum, and in the male straining from urethral obstruction, predispose to mucosal prolapse. In old age, both mucosal and full-thickness prolapse are associated with weakness of the sphincter mechanism, but whether this is the cause of the problem or secondary to it is unknown.

Partial prolapse may follow an operation for fistula in ano where a large portion of muscle has been divided. Here, the prolapse is usually localised to the damaged quadrant and is seldom progressive.

Prolapsed mucous membrane is pink; prolapsed internal haemorrhoids are plum coloured and more pedunculated.

### Treatment

**In infants and young children**
- Digital repositioning. The parents are taught to replace the protrusion, and any underlying causes are addressed.

**In adults**
- Local treatments. Submucosal injections of phenol in almond oil or the application of rubber bands are sometimes successful in cases of mucosal prolapse.
- Excision of the prolapsed mucosa. When the prolapse is unilateral, the redundant mucosa can be excised or, if circumferential, an endoluminal stapling technique can be used.

### Full-thickness prolapse

Full-thickness prolapse (synonym: procidentia) is less common than the mucosal variety. The protrusion consists of all layers of the rectal wall and is usually associated with a weak pelvic floor. The prolapse is thought to commence as an intussusception of the rectum, which descends to protrude outside the anus. The process starts with the anterior wall of the rectum, where the supporting tissues are weakest, especially in women. It is more than 4 cm and commonly as much as 10–15 cm in length (Figure 72.9). On palpation between the finger and thumb, the prolapse feels much thicker than a mucosal prolapse, and obviously consists of a double thickness of the entire wall of the rectum. Any prolapse over 5 cm in length contains anteriorly between its layers a pouch of peritoneum (Figure 72.10). When large, the peritoneal pouch may contain small intestine, which returns to the general peritoneal cavity with a characteristic gurgle when the prolapse is reduced. The anal sphincter is characteristically patulous and gapes widely on straining to allow the rectum to prolapse. Complete prolapse is uncommon in children. In adults, it can occur at any age, but it is more common in the elderly. Women are affected six times more often than men.
men, and it is commonly associated with prolapse of the uterus. In approximately 50 per cent of adults, faecal incontinence is also a feature.

**Differential diagnosis**

In the case of a child with abdominal pain, prolapse of the rectum must be distinguished from ileocaecal intussusception protruding from the anus. Figures 72.11 and 72.12 make the differential diagnosis clear. In rectosigmoid intussusception in the adult, there is a deep groove (5 cm or more) between the emerging protruding mass and the margin of the anus, into which the finger can be placed.

**Treatment**

Surgery is required, and the operation can be performed via the perineal or the abdominal approaches. An abdominal rectopexy has a lower rate of recurrence but, when the patient is elderly and very frail, a perineal operation, sometimes performed under spinal anaesthetic, is usually safer. As an abdominal procedure risks damage to the pelvic autonomic nerves, resulting in possible sexual dysfunction, a perineal approach is often preferred in young men.

**Perineal approach**

These procedures have been used most commonly:

- **Thiersch operation.** This procedure, which aimed to place a steel wire or, more commonly, a silastic or nylon suture around the anal canal, has become obsolete. The reasons for its lack of popularity were that the suture would often break or cause chronic perineal sepsis, or both, or the anal stenosis so created would produce severe functional problems.

- **Delorme’s operation.** In this procedure, the rectal mucosa is removed circumferentially from the prolapsed rectum over its length (Figure 72.13). The underlying muscle is then plicated with a series of sutures, so that, when these are tied, the rectal muscle is concertinaed towards the anal canal. The anal canal mucosa is then sutured circumferentially to the rectal mucosa remaining at the tip of the prolapse. The prolapse is reduced, and a ring of muscle is created above the anal canal, which prevents recurrence.

- **Altemeier’s procedure.** This consists of excision of the prolapsed rectum and associated sigmoid colon from below, and construction of a coloanal anastomosis.

**Abdominal approach**

The principle of all abdominal operations for rectal prolapse is to fix the rectum in its proper position. Many variations have been described, including inserting a sheet of polypropylene mesh between the rectum and the sacrum, hitching up the rectosigmoid junction with a Teflon sling to the front of the sacrum (Figure 72.14) or simply suturing the mobilised rectum to the sacrum using four to six interrupted non-absorbable sutures – so-called ‘sutured rectopexy’. Recently, the technique has been performed laparoscopically, thus reducing the operative trauma and limiting the time in hospital.

As an abdominal rectopexy may lead to severe constipation, some surgeons recommend combining this procedure with resection of the sigmoid colon, so-called ‘resection rectopexy’. Recently, an anterior mesh rectopexy has gained favour. In this procedure, a piece of mesh is fixed to the upper sacrum. The plane between the rectum and vagina is dissected, and the mesh placed into it and sutured to the rectum. This has the advantage of fixing the rectum in place anteriorly, where the prolapse starts, and reinforcing the rectovaginal septum which can bulge forward as a rectocele.

---

**Karl Thiersch**, 1822–1895, Professor of Surgery, Leipzig, Germany.

**Edmond Delorme**, 1847–1929, Professor of Surgery, Val-de-Grace Military Hospital, Paris, France.

**William Altemeier**, 1910–1983, Professor of Surgery, Cincinnati, USA.
SOLITARY RECTAL ULCER

This is becoming a more commonly diagnosed problem. Classically, it takes the form of an ulcer on the anterior wall of the rectum. In this form, it can be mistaken for a rectal carcinoma or inflammatory bowel disease, particularly Crohn’s disease. It may heal, leaving a polypoid appearance. Proctographic studies indicate that it is due to a combination of internal intussusception or anterior rectal wall prolapse and an increase in intrarectal pressure, usually caused by chronic straining as a result of constipation. The histological appearances confirm the diagnosis and are similar to the appearance of biopsies from a full-thickness overt rectal prolapse. The condition, although benign, is difficult to treat. Symptomatic relief from bleeding and discharge may sometimes be achieved by preventing the internal prolapse by biofeedback, an intrarectal stapling procedure or an abdominal rectopexy. In rare cases, rectal excision may be required.

PROCTITIS

Inflammation is sometimes limited to the rectum; in other cases, it is associated with a similar condition in the colon (proctocolitis). The inflammation can be acute or chronic. The symptoms are tenesmus and the passage of blood and mucus and, in severe cases, pus also. Although the patient has a frequent intense desire to defaecate, the amount of faeces passed at a time is small. Acute proctitis is usually accompanied by malaise and pyrexia. On rectal examination, the mucosa feels swollen and is often tender. Proctoscopy is seldom sufficient and sigmoidoscopy is the more valuable method of examination. If the diagnosis is confirmed, colonoscopy with multiple biopsies is mandatory to determine the extent of the inflammatory process. Skilled pathological assessment is required to establish or exclude the diagnosis of specific infection by bacteriological examination and culture of the stools, examination of scrapings or swabs from ulcers and serological tests.

Non-specific proctitis is an inflammatory condition affecting the mucosa and, to a lesser extent, the submucosa, confined to the distal rectum. In 10 per cent of cases, the condition extends to involve the whole colon (total ulcerative colitis) (Summary box 72.6).

Summary box 72.6

Proctitis

- May be non-specific or related to a specific infective agent
- Non-specific proctitis usually remains confined to the distal bowel, but can spread to the proximal colon
- Causes bleeding, diarrhoea and tenesmus
- Treatment is usually conservative

Aetiology

This is unknown. The concept that the condition is a mild and limited form of ulcerative colitis (although actual ulceration is often not present) is the most acceptable hypothesis.

Clinical features

The patient is usually middle-aged and complains of slight loss of blood in the motions. Often, the complaint is one of diarrhoea but, on closer questioning, it transpires that usually one relatively normal action of the bowels occurs each day, although it is accompanied by some blood. During the day, the patient attempts to defaecate, with the passage of flatus and a little blood-stained faecal matter, which is interpreted as diarrhoea. On rectal examination, the mucosa feels warm and smooth. Often, there is some blood on the examining finger. Proctoscopic and sigmoidoscopic examination shows inflamed mucosa of the rectum, but usually no ulceration. The inflammation usually extends for only 5–15 cm from the anus, with the mucosa above this level being normal.

Treatment

The condition is usually self-limiting, but treatment with topical 5-aminosalicylic acid (5-ASA) compounds (Asacol, Pentasa) in the form of suppositories or foam enemas is usually effective. Topical steroids are a less effective alternative. In very severe resistant cases, oral steroids may have to be used to obtain remission. Rarely, surgical treatment is required as a last resort when the patient is desperate for relief of symptoms.

Ulcerative proctocolitis

Proctitis is present in a high percentage of cases of ulcerative colitis, and the degree of severity of the rectal involvement may influence the type of operative procedure (see Chapter 69).

Proctitis due to Crohn’s disease

Crohn’s disease can occasionally affect the rectum, although classically it is spared. Sigmoidoscopic characteristics differ from those in non-specific proctitis. The inflammatory process tends to be patchy rather than confluent, and there may be fissuring, ulceration and even a cobblestone appearance. Rectal Crohn’s disease is often associated with severe perineal disease characterised by fistulation. Skip lesions are also often present in the rest of the colon or small bowel, or both.
Proctitis due to specific infections

*Clostridium difficile*
An acute form of proctocolitis caused by infection with *Clostridium difficile* can follow broad-spectrum antibiotic administration. A ‘membrane’ can sometimes be seen on proctoscopy (‘pseudomembranous’ colitis).

*Bacillary dysentery*
The appearance is that of an acute purulent proctitis with multiple small, shallow ulcers. The examination of a swab taken from the ulcerated mucous membrane is more certainly diagnostic than stool microscopy.

*Amoebic dysentery*
The infection is more liable to be chronic, and exacerbations after a long period of freedom from symptoms often occur. Proctoscopy and sigmoidoscopy are not painful. The appearance of an amoebic ulcer is described in Chapter 69. Scrapings from the ulcer should be immersed in warm isotonic saline solution and sent to the laboratory for immediate microscopic examination.

*Amoebic granuloma*
This presents as a soft mass, usually in the rectosigmoid region. This lesion is frequently mistaken for a carcinoma. Sigmoidoscopy shows an ulcerated surface, but the mass is less friable than a carcinoma. A scraping should be taken, preferably with a small, sharp spoon on a long handle, and the material sent for immediate microscopic examination, as detailed above. A biopsy can also help. Treatment is as described in Chapter 69. Amoebic granuloma of the rectum is encountered from time to time in a patient who has never visited a country in which the disease is endemic.

*Tuberculous proctitis*
This is nearly always associated with active pulmonary tuberculosis or tuberculous ulceration of the anus. Submucous rectal abscesses burst and leave ulcers with an undermined edge. A hypertrophic type of tuberculous proctitis occurs in association with tuberculous peritonitis, or tuberculous proctitis occurs in association with tuberculous peritonitis or tuberculous salpingitis. This type of tuberculous proctitis requires biopsy for confirmation of the diagnosis.

*Gonococcal proctitis*
Gonococcal proctitis occurs in both sexes as the result of rectal coitus and, in the female, from direct spread from the vulva. In the acute stage, the mucous membrane is hyperaemic, and thick pus can be expressed as the proctoscope is withdrawn. In the early stages, the diagnosis can be readily established by bacteriological examination but, later, when the infection is mixed, it is more difficult to recognise. Systemic treatment is so effective that local treatment is unnecessary.

*Lymphogranuloma venereum*
The modes of infection are similar to those of gonococcal proctitis but, in the female, chlamydial infection spreading from the cervix uteri via lymphatics to the pararectal lymph nodes is common. The proctological findings are similar to those of gonococcal proctitis. The diagnosis of lymphogranuloma venereum should be suspected when the inguinal lymph nodes are greatly enlarged, although the enlargement may be subsiding by the time proctitis commences.

Acquired immunoodeficiency syndrome
Acquired immunodeficiency syndrome (AIDS) due to human immunodeficiency virus (HIV) may present with a particularly florid type of proctitis. In such patients, unusual organisms such as cytomegalovirus (CMV), herpes simplex virus and organisms such as *Cryptosporidium* are often found.

‘Strawberry’ lesion of the rectosigmoid
This results from an infection by *Spirochaeta vincenti* and *Bacillus fusiformis*. The leading symptom is diarrhoea, often scantily blood-stained. Occasionally, the diagnosis can be made by the demonstration of the specific organisms in the stools. More often, sigmoidoscopy is required. The characteristic lesion is thickened, somewhat raised mucosa with superficial ulceration in the region of the rectosigmoid. The inflamed mucous membrane oozes blood at numerous pinpoints, giving the appearance of an over-ripe strawberry. A swab should be taken from the lesion and examined for Vincent’s and fusiform organisms. Swabs from the gums and the throat are also advisable.

Rectal bilharziasis
Rectal bilharziasis is caused by *Schistosoma mansoni*, which is endemic in many tropical and subtropical countries, and particularly in the delta of the Nile.

In stage 1, a cutaneous lesion develops at the site of entrance of the cercariae (parasites of freshwater snails). Stage 2 is characterised by pyrexia, urticaria and a high eosinophilia. Both these stages are frequently overlooked. Stage 3 results from deposition of the ova in the rectum (much more rarely in the bladder; Chapter 76) and is manifested by bilharzial dysentery. On examination in the later stages, papillomas are frequently present. The papillomas, which are sessile or pedunculated, contain the ova of the trematode, the life cycle of which resembles that of *Schistosoma haematobium*.

Untreated, the rectum becomes festooned, and prolapse of the diseased mucous membrane is usual. Multiple fistulae in ano are prone to develop.

Treatment
The primary treatment is systemic and should be undertaken by a specialist in tropical medicine. When the papillomas persist in spite of general treatment, they should be treated by local destruction.

Proctitis due to herbal enemas
This is a well-known clinical entity to those practising in tropical Africa. Following an enema consisting of a concoction of ginger, pepper and bark, administered by a witch doctor, a virulent proctitis sets in. Pelvic peritonitis frequently supervenes. Not infrequently, a complete gelatinous cast of the mucous membrane of the rectum is extruded. Very large doses of morphine, together with antibiotics, often prevent a fatal outcome if commenced early. Temporary colostomy is often advisable.
Treatment

General treatments should include bed rest in extreme cases. The stools should be kept soft. Suppositories of 5-ASA are often beneficial. Infective causes require specific treatment.

BENIGN TUMOURS

The rectum, along with the sigmoid colon, is the most frequent site of polyps (and cancers) in the gastrointestinal tract. Adenomatous polyps of the colon and rectum have the potential to become malignant. The chance of harbouring invasive cancer is enhanced if the polyp is more than 1 cm in diameter. Removal of all polyps is recommended to give complete histological examination and exclude (or confirm) carcinoma, and also to prevent local recurrence. This is best done using endoscopic hot biopsy or snare polypectomy techniques. If one or more rectal polyps are discovered on sigmoidoscopic examination, a colonoscopy must be performed, as further polyps are frequently found in the colon and treatment may be influenced. No rectal polyp should be removed until the possibility of a proximal carcinoma has been ruled out, otherwise local implantation of cancer cells may occur in the distally situated rectal wound.

The rectum shares substantially the same spectrum of polyps as the colon. Polyps are described chiefly in terms of their tissue organisation. Certain polyps that have features relevant to the rectum are now described.

Polyps relevant to the rectum

Villous adenomas

These have a characteristic frond-like appearance. They may be very large, and occasionally fill the entire rectum. These tumours have an enhanced tendency to become malignant – a change that can sometimes be detected by palpation with the finger; any hard area should be assumed to be malignant and should be biopsied. Rarely, the profuse mucous discharge from these tumours, which is rich in potassium, causes dangerous electrolyte and fluid losses (Figure 72.15).

Provided cancerous change has been excluded, these tumours can be removed by submucosal resection endoscopically, surgically per anum or by sleeve resection from above. Only very occasionally is rectal excision required. A technique known as transanal endoscopic microsurgery (TEM) has been developed, which has improved the endoanal approach for the local removal of villous adenomas. The method requires the insertion of a large operating sigmoidoscope. The rectum is distended by carbon dioxide insufflation, the operative field is magnified by a camera inserted via the sigmoidoscope, and the image is displayed on a monitor (Figure 72.16). The lesion is excised using specially designed instruments. The technique is highly specialised and takes a considerable amount of time to master.

Familial adenomatous polyposis

This autosomal dominantly inherited condition is characterised by the development of multiple rectal and colonic adenomas around puberty. It is due to mutation of the adenomatous polyposis coli (APC) gene, allowing genetic testing in the 75 per cent of families in which a mutation can be identified. A colonoscopy and biopsy will confirm the diagnosis. As this condition is premalignant, a total colectomy must be performed; often, the rectum can be preserved, but regular flexible endoscopy and removal of polyps before they develop carcinoma are required. The operation of restorative proctocolectomy with ileal pouch–anal anastomosis is an alternative if proctectomy is required: the rectum is replaced by a ‘pouch’ of folded ileum (Chapter 69). A pan-proctocolectomy with permanent ileostomy is necessary in some instances, especially when patient follow up may be impractical.

Hyperplastic polyps

These are small, pinkish, sessile polyps, 2–4 mm in diameter and frequently multiple. They are common and generally harmless.

Inflammatory pseudopolyps

These are oedematous islands of mucosa. They are usually associated with colitis in the UK, but most inflammatory diseases (including tropical diseases) can cause them. They are more likely to cause radiological difficulty as the sigmoidoscopic appearances are usually associated with obvious signs of the inflammatory cause.

Juvenile polyp

This is a bright-red glistening pedunculated sphere (‘cherry tumour’), which is found in infants and children. Occasionally, it persists into adult life. It can cause bleeding, or pain if it prolapses during defaecation. It often separates itself, but can be removed easily with forceps or a snare. A solitary juvenile polyp has virtually no tendency to malignant change, but should be treated if it is causing symptoms. It has a unique histological structure of large mucus-filled spaces covered by a smooth surface of thin rectal cuboidal epithelium (Figure 72.17). The rare autosomal dominantly inherited syndrome juvenile polyposis does confer an increased risk of gastrointestinal cancers. It is characterised by multiple juvenile polyps and a positive family history (Summary box 72.7).
Benign tumours

Summary box 72.7

Polyps in the rectum
- Are either single or multiple
- Adenomas are the most frequent histological type
- Villous adenomas may be extensive and undergo malignant change more commonly than tubular adenomas
- All adenomas must be removed to avoid carcinomatous change
- All patients must undergo colonoscopy to determine whether further polyps are present
- Most polyps can be removed by endoscopic techniques, but sometimes major surgery is required

Endometrioma
Endometrioma is rare and may be misdiagnosed as a carcinoma. The focus of ectopic endometrial tissue produces either a constricting lesion of the rectosigmoid or a tumour invading the rectum from the rectovaginal septum. The latter variety gives rise to a very tender submucous elevation of the rectal wall. Endometrioma occurs usually between 20 and 40 years of age. Dysmenorrhoea and rectal bleeding (particularly coinciding with the menses) are the main symptoms. On sigmoidoscopy, endometriosis involving the rectosigmoid junction usually presents as a stricture, with the mucous membrane intact. Hormonal manipulation is the first line of therapy, but sometimes total abdominal hysterectomy and bilateral salpingo-oophorectomy and even bowel resection is required.

Haemangioma
Haemangioma of the rectum is an uncommon cause of serious haemorrhage. When localised in the lower part of the rectum or
anal canal, a haemangioma can be excised. When the lesion is diffuse, or lying in the upper part of the rectum, the symptoms simulate ulcerative colitis, and the diagnosis is often missed for a long period, or it is mistakenly thought to be a carcinoma. Selective angiography and embolisation may be helpful, but excision of the rectum is sometimes required.

**Gastrointestinal stromal tumour**

Smooth muscle tumours of the rectum are rare. If the mitotic rate is high, and if there is variation in nuclear number, size and shape, hyperchromasia and frequent bizarre cells, these tumours are likely to metastasise. In these circumstances, they should be classified as malignant gastrointestinal stromal tumours (formerly leiomyosarcomas). The uncertainty in their behaviour means that treatment should, whenever possible, be by radical excision.

**CARCINOMAS**

Overall, colorectal cancer is the second most common malignancy in western countries, with approximately 18,000 patients dying per annum in the UK. The rectum is the most frequent site involved.

**Origin**

It is now accepted that colorectal cancer arises from adenomas in a stepwise progression in which increasing dysplasia in the adenoma is due to an accumulation of genetic abnormalities (the adenoma–carcinoma sequence). In approximately 5 per cent of cases, there is more than one carcinoma present. Usually, these carcinomas present as an ulcer, but polypoid and infiltrating types are also common.

**Types of carcinoma spread**

**Local spread**

Local spread occurs circumferentially rather than in a longitudinal direction. After the muscular coat has been penetrated, the growth spreads into the surrounding mesorectum, but is initially limited by the mesorectal fascia. If penetration occurs anteriorly, the prostate, seminal vesicles or bladder become involved in the male; in the female, the vagina or the uterus is invaded. In either sex, if the penetration is lateral, a ureter may become involved, while posterior penetration may reach the sacrum and the sacral plexus. Downward spread for more than a few centimetres is rare.

**Lymphatic spread**

Lymphatic spread from a carcinoma of the rectum above the peritoneal reflection occurs almost exclusively in an upward direction; below that level, the lymphatic spread is still upwards, but when the neoplasm lies within the field of the middle rectal artery, primary lateral spread along the lymphatics that accompany it is not infrequent.

Downward spread is exceptional, with drainage along the subcutaneous lymphatics to the groins being confined, for practical purposes, to the lymph nodes draining the perianal rosette and the epithelium lining the distal 1–2 cm of the anal canal.

Metastasis at a higher level than the main trunk of the superior rectal artery occurs only late in the disease. A radical operation should ensure that the high-lying lymph nodes are removed by ligating the inferior mesenteric artery at a high level. Atypical and widespread mesenteric artery may occur in highly undifferentiated neoplasms.

**Venous spread**

The principal sites for blood-borne metastases are liver (34 per cent), lungs (22 per cent) and adrenals (11 per cent). The remaining 33 per cent are divided among the many other locations where secondary carcinomatous deposits tend to lodge, including the brain.

**Peritoneal dissemination**

This may follow penetration of the peritoneal coat by a high-lying rectal carcinoma.

**Stages of progression**

Dukes classified carcinoma of the rectum into three stages (Figure 72.18).

**Dukes’ staging**

- **A**, The growth is limited to the rectal wall (15 per cent): prognosis excellent (90 per cent year survival).
- **B**, The growth is extended to the extrarectal tissues, but no metastasis to the regional lymph nodes (35 per cent): prognosis reasonable (70 per cent year survival).
- **C**, There are secondary deposits in the regional lymph nodes (50 per cent). These are subdivided into C1, in which the local pararectal lymph nodes alone are involved, and C2, in which the nodes accompanying the supplying blood vessels are implicated up to the point of division. This does not take into account cases that have metastasised beyond the regional lymph nodes or by way of the venous system: prognosis is poor (40 per cent year survival).

A stage D is often included, which was not described by Dukes. This stage signifies the presence of widespread metastases, usually hepatic.

![Figure 72.18 The three cardinal stages of progression of the neoplasm (after C Dukes, FRCS).](image-url)
Other staging systems have been developed (e.g. Astler–Coller, TNM) to improve prognostic accuracy, but the tumour–node–metastasis (TNM) classification is now recognised internationally as the optimum classification for staging.

**TNM staging**

T represents the extent of local spread and there are four grades:
- **T1** tumour invasion through the muscularis mucosae, but not into the muscularis propria;
- **T2** tumour invasion into, but not through the muscularis propria;
- **T3** tumour invasion through the muscularis propria, but not through the serosa (on surfaces covered by peritoneum) or mesorectal fascia;
- **T4** tumour invasion through the serosa or mesorectal fascia.

N describes nodal involvement:
- **N0** no lymph node involvement;
- **N1** between one and three involved lymph nodes;
- **N2** four or more involved lymph nodes.

M indicates the presence of distant metastases:
- **M0** no distant metastases;
- **M1** distant metastases.

The prefix ‘p’ indicates that the staging is based on histopathological analysis, and ‘y’ that it is the stage after neoadjuvant treatment, which may have resulted in downstaging.

**Histological grading**

In the great majority of cases, carcinoma of the rectum is a columnar-celled adenocarcinoma. The more nearly the tumour cells approach normal shape and arrangement, the less aggressive the tumour is. Conversely, the greater the percentage of cells of an undifferentiated type, the more aggressive the tumour is:
- Low grade, well-differentiated 11 per cent prognosis good;
- Average grade, 64 per cent prognosis fair;
- High grade, undifferentiated tumours 25 per cent prognosis poor.

Vascular and perineural invasion are poor prognostic features, as is the presence of an infiltrating (rather than pushing) margin and tumour budding. In a small number of cases, the tumour is a primary mucoid carcinoma. The mucus lies within the cells, displacing the nucleus to the periphery, like the seal of a signet ring. Primary mucoid carcinoma gives rise to a rapidly growing bulky growth that metastasises very early and the prognosis of which is very poor (Summary box 72.8).

**Clinical features**

Carcinoma of the rectum can occur early in life, but the age of presentation is usually above 55 years, when the incidence rises rapidly. Often, the early symptoms are so insignificant that the patient does not seek advice for six months or more (Summary box 72.9), and the diagnosis is often delayed in younger patients as these symptoms are attributed to benign causes. Initial rectal examination and a low threshold for investigating persistent symptoms are essential to prevent this.

**Summary box 72.8**

**Pathology and staging of rectal cancer**

- Tumours are adenocarcinomas and are well, moderately or poorly differentiated
- They spread by local, lymphatic, venous and transperitoneal routes
- Circumferential local spread is the most important as this profoundly affects surgical treatment
- Although lymphatic spread follows the blood supply of the rectum, most occurs in an upwards direction via the superior rectal vessels to the para-aortic nodes
- The TNM classification is the internationally recognised staging system

**Summary box 72.9**

**Early symptoms of rectal cancer**

- Bleeding per rectum
- Tenesmus
- Early morning diarrhoea

**Bleeding**

Bleeding is the earliest and most common symptom. There is nothing characteristic about the time at which it occurs, nor is the colour or the amount of blood distinctive; often, the bleeding is slight in amount and occurs at the end of defeacation, or is noticed because it has stained underclothing. Indeed, more often than not, the bleeding in every respect simulates that of internal haemorrhoids (haemorrhoids and carcinoma sometimes coexist).

**Sense of incomplete defaecation**

The patient’s bowels open, but there is the sensation that there are more faeces to be passed (tenesmus, a distressing straining to empty the bowels without resultant evacuation). This is a very important early symptom and is almost invariably present in tumours of the lower half of the rectum. The patient may endeavour to empty the rectum several times a day (spurious diarrhoea), often with the passage of flatus and a little blood-stained mucus (‘bloody slime’).

**Alteration in bowel habit**

This is the next most frequent symptom. The patient may find it necessary to start taking an aperient or to supplement the usual dose. A patient who has to get up early in order to defaecate, or one who passes blood and mucus in addition to faeces (‘early-morning bloody diarrhoea’), is usually found to be suffering from carcinoma of the rectum. Often, it is the patient with an annular carcinoma at the rectosigmoid junction who suffers with increasing constipation, and the one with a growth in the ampulla of the rectum who has early-morning diarrhoea.

**Pain**

Pain is a late symptom, but pain of a colicky character may accompany advanced tumours of the rectosigmoid, and is caused...
by some degree of intestinal obstruction. When a deep carcinomaous ulcer of the rectum erodes the prostate or bladder, there may be severe pain. Pain in the back, or sciatica, occurs when the cancer invades the sacral plexus.

Weight loss is suggestive of hepatic metastases.

Investigation

Abdominal examination
Abdominal examination is normal in early cases. Occasionally, when an advanced annular tumour is situated at the rectosigmoid junction, signs of obstruction of the large intestine are present. By the time the patient seeks advice, metastases in the liver may be palpable. When the peritoneum has become studied with secondary deposits, ascites usually results.

Rectal examination
In many cases, the neoplasm can be felt digitally: in early cases as a nodule with an indurated base. When the centre ulcerates, a shallow depression will be found, the edges of which are raised and everted. On bimanual examination, it may be possible to feel the lower extremity of a carcinoma situated in the rectosigmoid junction. After the finger has been withdrawn, if it has been in direct contact with a carcinoma, it is smeared with blood or mucopurulent material tinged with blood. When a carcinomaous ulcer is situated in the lower third of the rectum, involved lymph nodes can sometimes be felt as one or more hard, oval swellings in the mesorectum posteriorly or posterolaterally above the tumour. In females, a vaginal examination should be performed and, when the neoplasm is situated on the anterior wall of the rectum, with one finger in the vagina and another in the rectum, very accurate palpation can be carried out.

Proctosigmoidoscopy
Proctosigmoidoscopy will always show a carcinoma, if present, provided that the rectum is emptied of faeces beforehand.

Biopsy
Using biopsy forceps (Figure 72.19) via a sigmoidoscope, a portion of the edge of the tumour can be removed. If possible, another specimen from the more central part of the growth should also be obtained.

Colonoscopy
A colonoscopy is required if possible in all patients to exclude a synchronous tumour, be it an adenoma or a carcinoma. If a proximal adenoma is found, it can be conveniently snared and removed via the colonoscope. If a synchronous carcinoma is present, the operative strategy will need changing. If a synchronous tumour, be it an adenoma or a carcinoma, if possible, a CT colonography or barium enema can be performed.

When a stenosing carcinoma is present, it may not be possible using these investigations, especially colonoscopy, to visualise the proximal colon. However, in view of the high incidence of synchronous tumours, it is imperative that a colonoscopy is always performed either before or within a few months of surgical resection.

Differential diagnosis
When an adenoma shows evidence of induration or unusual friability, it is almost certain that malignancy has occurred, even in spite of biopsy findings to the contrary. On the other hand, biopsy is invaluable in distinguishing carcinoma from an inflammatory stricture or an amoebic granuloma. The possibility of a neoplasm being an endometrioma should always be considered in patients with dysmenorrhoea. The possibility of a carcinoid tumour in atypical cases must be remembered. In the last four instances, biopsy should establish the correct diagnosis. The solitary ulcer syndrome has already been mentioned above (Summary box 72.10).

Summary box 72.10

Diagnosis and assessment of rectal cancer
All patients with suspected rectal cancer should undergo:

- Digital rectal examination
- Sigmoidoscopy and biopsy
- Colonoscopy if possible (or CT colonography or barium enema)

All patients with proven rectal cancer require staging by:

- Imaging of the liver and chest, preferably by CT
- Local pelvic imaging by magnetic resonance imaging and/or endoluminal ultrasound

Treatment
Some form of excision of the tumour remains the mainstay of treatment, if at all possible, because of the extreme suffering entailed if the neoplasm remains. However, the management of rectal cancer has become increasingly complex, because of the various surgical, neoadjuvant and adjuvant options available, and is best delivered in a multidisciplinary setting. Before treatment can be planned, it is necessary to assess:

- the fitness of the patient;
- the extent of spread of the tumour.

Assessment of spread should include CT of the chest and abdomen to exclude distant metastases (Figure 72.20). Ultrasonography of the liver and a chest radiograph are decreasingly used alternatives. Positron emission tomography (PET) scanning can be helpful in identifying metastases if imaging is otherwise equivocal.

Endoluminal ultrasound, performed using a probe placed in the rectal lumen, can be used to assess the local spread of the tumour (Figure 72.21), and is particularly accurate in staging the degree of penetration through the rectal wall in early tumours. CT is not particularly accurate in local staging, which is usually performed using magnetic resonance imaging (MRI), which allows assessment of the circumferential resection margin and adjacent structures (Figure 72.22).
Principles of surgical treatment

Radical excision of the rectum, together with the mesorectum and associated lymph nodes, should be the aim in most cases. Even in the presence of widespread metastases, a rectal excision should be considered, as this is often the best means of palliation. The presence of liver metastases does not necessarily rule out the feasibility of cure: the results of surgery for liver metastases have greatly improved, with long-term survival being achieved in over a third of patients.

When a tumour appears to be locally advanced (i.e. invading a neighbouring structure or threatening to breach the circumferential resection margin), the administration of a course of neoadjuvant (preoperative) chemoradiotherapy over approximately 6 weeks may reduce its size and make curative surgery possible. The administration of preoperative ‘short-course’ (5 days) neoadjuvant radiotherapy in resectable rectal cancer cases significantly reduces the incidence of local recurrence, but at the cost of some increase in complication rates.

For patients who are unfit for radical surgery, who have very early tumours or who have widespread metastases, a local procedure such as transanal excision, laser destruction or interstitial radiation should be considered.

When a rectal excision is possible, the aim should be to restore gastrointestinal continuity and continence by preserving the anal sphincter whenever feasible. A sphincter-saving operation (anterior resection) is usually possible for tumours whose lower margin is ≥2 cm above the anal canal. Although removal of the rectum and anus with a permanent colostomy (abdominoperineal excision) was often required for tumours of the lower third of the rectum in the past, the introduction of the stapling gun has enabled many more of these patients to be treated by a sphincter-saving procedure. The principles of the operation involve radical excision of the neoplasm, removal of the mesorectum that surrounds it and high proximal ligation of the inferior mesenteric lymphovascular pedicle. Once the rectum has been adequately mobilised, it is removed, and the rectal stump is washed out. Restoration of continuity by direct end-to-end anastomosis (manually or by stapling) must be carried out by a meticulous technique to reduce the risks of anastomotic breakdown.

Rectosigmoid tumours and those in the upper third of the rectum are removed by ’high anterior resection’, in which the rectum and mesorectum are taken to a margin 5 cm distal to the tumour, and a colorectal anastomosis is performed. This does not usually require defunctioning. The retention of at least a part of the rectum results in good postoperative function.

For tumours in the middle and lower thirds of the rectum, complete removal of the rectum and mesorectum is required, i.e. total mesorectal excision (TME). A temporary protecting stoma is usually formed after TME (see below under Anterior resection).

Preoperative preparation

Traditionally, the bowel was prepared by mechanical cleansing using a combination of diet, purgatives and enemas (e.g. senna,
Picola). This approach is now used more selectively, with many surgeons reserving full bowel preparation for those undergoing a low anterior resection, and clearing only the distal bowel using enemas in the rest. Prophylactic systemic antibiotics are given preoperatively. The antibiotic regimen must be active against both aerobic and anaerobic organisms. At present, a suitable prescription would be cefuroxime 750 mg plus metronidazole 500 mg given on induction of anaesthesia. If a patient comes to surgery with a loaded colon, on-table intraoperative irrigation can be performed.

All patients should see a stoma care nurse preoperatively and be sited for a temporary or permanent ileostomy or colostomy. They must also be counselled as to the complications of the procedure, and particularly about the risks of pelvic autonomic nerve damage causing bladder and sexual disturbance, especially impotence.

Blood and electrolyte deficiencies are corrected. Before commencing the operation, an indwelling catheter is inserted into the bladder (Summary box 72.11).

**Summary box 72.11**

**Preoperative preparation**
- Counselling and siting of stomas
- Correction of anaemia and electrolyte disturbance
- Cross-matching of blood
- Bowel preparation
- Deep vein thrombosis prophylaxis
- Prophylactic antibiotics
- Insertion of urinary catheter

**Local operations**

For small, low-grade T1 tumours, local removal should be curative in the vast majority; only a small percentage of these will have involved lymph nodes which are left undetected and unremoved by this approach. For these tumours, especially in the unfit or in patients who will not accept a colostomy, local removal has been used. This is usually done via the anus and the TEM technique is often used.

There is considerable controversy, however, as to whether such local techniques should be used for potentially curable lesions as they do not allow full histopathological staging or deal with the mesorectal or lymphatic spread of the tumour. Certainly the local recurrence rate (mostly due to lymph node metastases within the mesorectum) after local excision of T2 tumours is in the region of 20 per cent, which is unacceptable in all but those in whom radical surgery is associated with very high risk. Combined local excision with chemotherapy and radiotherapy has been suggested as a curative treatment for T1 and T2 tumours, but is not widely accepted.

**Anterior resection**

In the last 30 years, there has been a move to extend sphinctersaving operations to treat most tumours of the middle third of the rectum, and indeed many in the lower third. Over the last five years it has become clear that this surgery can be performed laparoscopically with at least equivalent oncological outcomes. This is, however, technically challenging and should only be performed in this way by adequately trained and experienced surgeons.

Following a midline incision, the liver and the peritoneum are examined for metastases. The sigmoid and descending colon are freed by dividing the peritoneal reflection on the left side and mobilised to the midline on their mesentery. The splenic flexure is dissected and the left ureter and testicular or ovarian vessels are identified. The mesocolon is divided at the site of the proposed division of the colon and the trunk of the inferior mesenteric artery (Figure 72.23) is ligated and divided. Most surgeons divide the descending colon at this point.

The rectosigmoid mesentery is separated from the sacrum by sharp dissection with scissors or, more usually, diathermy. Great care is exercised to ensure that the hypogastric nerves are identified and preserved. It is essential that, as the distal dissection proceeds, the surgeon remains outside the mesorectal fascia and stays within the bloodless ‘holy’ plane outside it. The peritoneal incision is carried anteriorly around the rectum, and the seminal vesicles or the vaginal wall are identified so that Denonvilliers’ fascia behind them is cleared by a dissection leading down to the prostate or vagina. The condensations of fascia that attach the rectum to the pelvic side walls and are known as the lateral ligaments are dissected by diathermy. This tissue contains the middle rectal vessels, which sometimes require separate ligation and division.

The rectum is mobilised to the pelvic floor, and a right-angled clamp is placed at least 1 cm below the tumour. The rectum can then be stapled transversely. After the rectum and sigmoid colon have been excised, continuity is re-established by the method depicted in Figure 72.24. Although a single loop of colon is often used for the anastomosis, a short J-shaped colonic pouch may be...

---

**Figure 72.23** Exposure and division of the inferior mesenteric vessels flush with the aorta (high tie) in the course of an abdominoperineal excision of the rectum. Redrawn with permission from Keighley MRB, Williams NS. Surgery of the anus, rectum and colon. London: WB Saunders, 1999.
constructed with the aim of increasing neorectal capacity and thus reducing postoperative bowel frequency and urgency. Many surgeons believe that such a temporary defunctioning stoma is required for all colorectal and coloanal anastomoses that are constructed below the peritoneal reflection.

Occasionally, although the rectum, together with its tumour, can be removed adequately, continuity cannot be restored by a stapling technique. In such cases, it may still be possible to restore continuity by bringing the colon down to the anal canal and constructing a sutured coloanal anastomosis via the transanal route (Figure 72.25).

It is important to ensure that any free tumour cells released by mobilisation of the rectum are destroyed by irrigation of the rectal lumen with a cancercidal solution such as 1 per cent cetrimide. By so doing, the implantation of such cells and subsequent local recurrence is prevented. However, it should be realised that, although a small percentage of local recurrences are due to implantation of shed cells, the majority result from inadequate removal of the tumour at the time of the initial operation. It is now known that micrometastases are present in the mesorectum, and these are the most likely cause of local recurrence after rectal excision. It is essential to remove all the mesorectum during anterior resection or abdominoperineal

Figure 72.24 Low anterior resection by the double stapling method. The rectum has been excised, and the distal anorectal stump has been transected with a transverse stapling device. A circular stapling gun is used to construct (a) a straight low coloanal anastomosis or (b) a colonic pouch–anus anastomosis.

Figure 72.25 Abdominotransanal–coloanal anastomosis. (a) The rectum has been excised, and the mucosa from the distal anorectal stump has been removed, leaving the rectal muscle intact. The proximal colon has been brought down through the rectal muscular cuff to be anastomosed to the anal mucosa via the transanal route. (b) The completed coloanal anastomosis. A covering ileostomy has been performed to allow the anastomosis to heal.
excision, the procedure known as TME. TME is now being practised worldwide and appears to reduce the risks of local recurrence substantially (Figure 72.26). This has been largely due to the work of Heald, who has shown that training in the technique improves local recurrence rates, and has been central to its widespread adoption. However, it is unlikely that surgery alone will deal adequately with all the micrometastases in the pelvis. Consequently, neoadjuvant radiotherapy may have added benefit (see below under Radiotherapy).

**Hartmann’s operation**

This is an excellent procedure in an old and frail patient in whom there is concern about anal sphincter function or the viability of an anastomosis. Through an abdominal incision, the rectum is excised, the anorectal stump is transected, usually with a stapler and an end colostomy is formed.

**Abdominoperineal excision of the rectum**

This operation is still required for some tumours of the lower third of the rectum, which are unsuitable for a sphincter-saving procedure. A large catheter is passed to allow easy identification of the urethra. Traditionally, the procedure was performed by two surgeons operating simultaneously, one via the abdomen and the other via the perineum with the patient in the Trendelenburg lithotomy position. More recently, there has been a shift to completing the abdominal procedure first (with the patient in the Lloyd-Davies position, in which the legs are in supports set lower than the lithotomy position), and then placing the patient prone and completing the operation via the perineum from behind (cylindrical or extra-levator abdominoperineal excision). There is evidence that this allows a wider dissection at the level of the pelvic floor, increasing complete resection rates and reducing local recurrence, although increasing morbidity.

The abdominal procedure is carried out laparoscopically or via a midline laparotomy, and is performed in the same way as an anterior resection, except that dissection stops before the pelvic floor is reached (at the level of the seminal vesicles in men or the cervix in women), to avoid ‘coning down’ onto the tumour at the level of the pelvic floor. The end colostomy is formed and the wounds closed.

The site for the colostomy in the left iliac fossa should have been marked preoperatively by the stoma care nurse in consultation with the patient. If this has not been possible, it should be sited equidistant from the umbilicus and the left anterior superior iliac spine at the linea semilunaris.

The perineal procedure is then carried out via an elliptical incision between the tip of the coccyx and the central perineal point around the anus. This is deepened until the pelvic floor is reached. This is divided as far laterally as possible, to maximise clearance of the tumour, which will be lying at this level (Figure 72.27). The dissection is extended posteriorly by incising Waldeyer’s fascia, which is a thick condensation of pelvic fascia lying between the rectum and the sacrum. Some surgeons routinely remove the coccyx to improve access and surgical margins. The dissection is deepened until the mobilisation performed via the abdomen is reached posteriorly and laterally. The plane between the rectum and the prostate in the male or between the rectum and the vagina in the female is developed, with particular care to avoid the membranous urethra in the male. The catheter within it should be palpated so that it can be avoided. The posterior wall of the vagina can be excised with the rectum if an advanced anterior tumour is present. The whole of the anus and rectum is drawn downwards and removed through the perineal wound.

**Care of the colostomy**

This is much the same as care of an ileostomy (Chapter 69). Within a very short time, the colostomy acts once or twice a day. Many patients are now taught to empty their lower colon by irrigation through the colostomy: this has many advantages for the patient who requires an inactive colostomy while at work.

**Endoluminal stenting**

An increasingly used alternative is placement of an endoluminal stent, which can be done endoscopically, often with fluoroscopic guidance. This can either be used as a palliative procedure, or to relieve obstruction and permit elective rather than emergency surgery to be undertaken. Only colonic and upper rectal tumours are suitable for stenting.

**Palliative colostomy**

This is indicated only in cases giving rise to intestinal obstruction, or where there is gross infiltration of the neoplasm. It is sometimes possible to resect the tumour later (e.g. after chemoradiotherapy) and, in some cases, cure, rather than palliation, is achieved.
Other palliative procedures

Occasionally, a neodymium:yttrium–aluminium–garnet (Nd: YAG) laser can be used to deal with an obstructing or bleeding lesion, and intraluminal debulking has also been described.

More extensive operations

When the carcinoma of the rectum has spread to contiguous organs, the radical operation can often be extended to remove these structures. Thus, in the male, in whom spread is usually to the bladder, a cystectomy and resection of the rectum can be performed. In the female, the uterus acts as a barrier, usually preventing spread from the rectum to the bladder. Accordingly, a hysterectomy should be undertaken in addition to excision of the rectum. Pelvic evisceration for carcinoma of the rectum is justifiable only when the surgeon is confident that the growth can be completely removed.

Pelvic exenteration (Brunschwig’s operation)

The aim is to remove all the pelvic organs, together with the internal iliac and the obturator groups of lymph nodes (Figure 72.28). Ligation of both internal iliac arteries diminishes the blood loss. A rectus abdominis flap can be used to fill the empty pelvis. Special care must therefore be taken to suture the perineal skin accurately, and to avoid pressure necrosis of the perineal incision by nursing the patient on alternate sides. Some form of urinary diversion is necessary, usually an ileal conduit.

Liver resection

Single or several well-localised liver metastases can now be resected with relatively low mortality and morbidity. Provided the patients are carefully selected, a reasonable long-term prognosis can be anticipated.

survival rate can be achieved (approximately 40 per cent in some series). Such surgery is usually carried out in a specialised liver unit, and it is generally advised that it takes place after the primary lesion has been dealt with (Summary box 72.12).

### Summary box 72.12

**Surgery for rectal cancer**
- Surgery is the mainstay of curative therapy
- The primary resection consists of rectal excision with total mesorectal excision
- Most cases can be treated by anterior resection with the colorectal anastomosis being achieved with a circular stapling gun
- A smaller group of low, extensive tumours require an abdominoperineal excision with a permanent colostomy
- Preoperative radiotherapy can reduce local recurrence
- Adjuvant chemotherapy can improve survival in node-positive disease
- Liver resection in carefully selected patients offers the best chance of cure for single or well-localised liver metastases

### Radiotherapy

Various trials have been performed to investigate the effect of adjuvant radiotherapy given either pre- or postoperatively. The overall results suggest that, provided an adequate dose is given, neoadjuvant radiotherapy can reduce the incidence of local recurrence; however, long-term survival is not affected. Recent studies have combined radiotherapy with chemotherapy in an attempt to shrink an extensive tumour prior to surgical excision. In some cases using this combined therapy, the results can be spectacular, and it has become the standard initial treatment for locally advanced tumours, allowing potentially curative resection in cases that would otherwise be inoperable. Indeed, in a few cases, the tumour appears to respond completely, making the approach to further management controversial.

Palliative irradiation can be given for inoperable primary tumours or local recurrence, especially when painful. Papillon refined a technique of intracavity radiation that applies the treatment direct to the tumour from the rectal lumen. In a selected series of early cases, the results were good (five-year survival rates of more than 70 per cent).

### Chemotherapy

A variety of drugs has been tried both as an adjuvant therapy and for the treatment of disseminated disease. The most frequently used drug is 5-fluorouracil (5-FU) or its oral equivalent capecitabine. There is now good evidence that systemic 5-FU alone or in combination with oxaliplatin can improve survival by 10–15 per cent in node-positive disease. Similarly, studies in which 5-FU has been infused into the portal vein during and immediately after the primary operation have shown a small benefit. Such intraportal adjuvant therapy is thought to kill malignant cells, which are released into the circulation during operative manipulation of the tumour, and thus prevent the formation of metastases. Recently, some exciting new drugs have become available, the most notable being irinotecan and cetuximab. Both agents have been shown to have a moderate but beneficial effect in disseminated disease, but it remains to be seen whether they will be effective in an adjuvant setting.

### Results of surgery for rectal cancer

In specialised centres, the resectability rate may be as high as 95 per cent, with an operative mortality of less than 5 per cent. Overall, the five-year survival rate is about 50 per cent.

Survival rates are influenced by TNM/Dukes’ stage, with node-positive patients doing worse than those with node-negative lesions (Figure 72.29). The bowel cancer screening programmes being introduced in many countries will result in earlier stage at presentation, and consequently improved outcome. The lower the tumour is in the rectum, the worse the outlook. Histological grade also influences outcome, with undifferentiated lesions having the worse prognosis.

### Local recurrence

Local recurrence after rectal excision is a major problem. The patient often presents with persistent pelvic pain, which radiates down the legs if the sacral roots are involved. Bladder symptoms may occur. If recurrence develops after abdominoperineal excision, a swelling or induration may be present in the perineum, or an abscess or discharging sinus may develop. After sphinctersaving resection, there may be a change in bowel habit or the passage of blood per rectum. Sigmoidoscopic examination may reveal friable tissue at the anastomosis which, when biopsied, confirms the diagnosis. However, the recurrence is usually situated extrarectally, and is detected either as induration on digital examination or by endoluminal ultrasonography, CT or MRI. These investigations can also detect recurrence before it causes symptoms. Local recurrence rates vary between 2 and 25 per cent and are higher after abdominoperineal excision than after sphinctersaving resection. The most common cause is inadequate removal of the whole tumour at the initial operation. This is due to the presence of microscopic tumour deposits in

![Figure 72.29](image-url)
the mesorectum. If the mesorectum is removed in its entirety, the local recurrence rate can be reduced to less than 5 per cent.

Less common causes of local recurrence include implantation of viable cells on the suture line and the development of a new primary tumour. Eighty per cent of all local recurrences develop within two years following surgery, and they are very difficult to treat. The best prospect of salvage is by surgical resection. However, it is possible to achieve apparently complete removal in only a minority of cases, and will usually involve hysterectomy, bladder resection and even partial sacrectomy. Radiotherapy also has an important role, but many patients will have already been exposed to a maximal dose during the treatment of the primary tumour.

**Carcinoid tumour**

Carcinoid tumour originates in the submucosa, with the mucous membrane over it being intact. Consequently, it seldom produces evidence of its presence in the early stages, when it presents as a small plaque-like elevation. The incidence of clinical malignancy, i.e. the occurrence of metastases, is 10 per cent. This is much less than that for carcinoid tumour of the small intestine, but it is greater than that for carcinoid tumour of the appendix. Multiple primary carcinoid tumours of the rectum are not infrequent. The neoplasm is of slow progression, and usually metastasises late. Large carcinoids (over 2 cm) are almost always malignant.

**Treatment**

Local excision is sufficient treatment for small carcinoids. Resection of the rectum is advisable if the growth is more than 2.5 cm in diameter, if recurrence follows local excision or if the growth is fixed to the perirectal tissues. Even when metastases are present, resection may prolong life.

PART 11
ABDOMINAL

CHAPTER
73

The anus and anal canal

LEARNING OBJECTIVES

To understand:

- The anatomy of the anus and anal canal and their relationship to surgical disease and its treatment
- The pathology, clinical presentation, investigation, differential diagnosis and treatment of diseases that affect the anus and anal canal

- That anal disease is common and its treatment tends to be conservative, although surgery may be required
- That too aggressive or inappropriate surgery may render the patient permanently disabled

ANATOMY AND PHYSIOLOGY

Surgical anatomy

The anal canal commences at the level where the rectum passes through the pelvic diaphragm and ends at the anal verge. The muscular junction between the rectum and anal canal can be felt with the finger as a thickened ridge – the anorectal ‘bundle’ or ‘ring’.

Anal canal anatomy

The anorectal ring

The anorectal ring marks the junction between the rectum and the anal canal (Figure 73.1). It is formed by the joining of the puborectalis muscle (Figure 73.2), the deep external sphincter, conjoined longitudinal muscle and the highest part of the internal sphincter. The anorectal ring can be clearly felt digitally, especially on its posterior and lateral aspects.

The puborectalis muscle

Puborectalis, part of the funnel-shaped muscular pelvic diaphragm, maintains the angle between the anal canal and rectum and hence is an important component in the continence mechanism (Figure 73.2). The muscle derives its nerve supply from the sacral somatic nerves, and is functionally indistinct from the external anal sphincter. The position and length of the anal canal, as well as the angle of the anorectal junction, depend to a major extent on the integrity and strength of the puborectalis muscle sling. It gives off fibres that contribute to the longitudinal muscle layer.

The external sphincter

The external sphincter forms the bulk of the anal sphincter complex and, although traditionally it has been subdivided into deep, superficial and subcutaneous portions, it is a single muscle (Goligher), which is variably divided by lateral extensions from the longitudinal muscle layer. Some of its fibres are attached posteriorly to the coccyx, whereas anteriorly they fuse with the perineal musculature. Being a somatic voluntary muscle, the external sphincter is red in colour and is innervated by the pudendal nerve.

John Cedric Goligher, 1912–1998, Professor of Surgery, University of Leeds, Leeds, UK. Goligher is reputed to have said to his staff: ‘It is a simple system here: if you do not agree with the style or requirements of the man above you, leave’.

Figure 73.1 Relevant anatomy of the anus. Redrawn with permission from Mann CV. Surgical treatment of haemorrhoids. London: Springer, 2002.
The intersphincteric plane

Between the external sphincter muscle laterally and the longitudinal muscle medially exists a potential space, the intersphincteric plane. This plane is important as it contains intersphincteric anal glands (see below under The anal glands) and is also a route for the spread of pus, which occurs along the extensions from the longitudinal muscle layer. The plane can be opened up surgically to provide access for operations on the sphincter muscles.

The longitudinal muscle

The longitudinal muscle is a direct continuation of the smooth muscle of the outer muscle coat of the rectum, augmented in its upper part by striated muscle fibres originating from the medial components of the pelvic floor. Most of the muscle continues caudally before splitting into multiple terminal septa that surround the muscle bundles of the subcutaneous portion of the external sphincter to insert into the skin of the lowermost part of the anal canal and adjacent perianal skin. Milligan and Morgan named the most medial of these septa, passing around the inferior border of the internal sphincter, the ‘anal intersmuscular septum’. As it descends, however, it gives off fibres that pass medially across the internal sphincter to reach the submucosal space, and laterally across the external sphincter and ischiorectal space to reach the fascia of the pelvic side walls. As well as providing a supportive mesh for the anal canal and other muscular components, its ramifications provide potential pathways for the spread of infection. During defaecation, its contraction widens the anal lumen, flattens the anal cushions, shortens the anal canal and everts the anal margin; subsequent relaxation allows the anal cushions to distend and thus contribute to an airtight seal.

The internal sphincter

The internal sphincter is the thickened (2–5 mm) distal continuation of the circular muscle coat of the rectum, which has developed special properties and which is in a tonic state of contraction. This involuntary muscle commences where the rectum passes through the pelvic diaphragm and ends above the anal orifice, its lower border palpable at the intersphincteric groove, below which lie the most medial fibres of the subcutaneous external sphincter, and separated from it by the anal intermuscular septum. When exposed during life, it is pearly-white in colour and its circumferentially placed fibres can be seen clearly. Although innervated by the autonomic nervous system, it receives intrinsic non-adrenergic and non-cholinergic (NANC) fibres, stimulation of which causes release of the neurotransmitter nitric oxide, which induces internal sphincter relaxation.

The epithelium and subepithelial structures

The pink columnar epithelium lining the rectum extends through the anorectal ring into the surgical anal canal. Passing downwards, the mucous membrane becomes cuboidal and redder in colour (Figure 73.3), whereas above the anal valves it is plum coloured. Just below the level of the anal valves there is an abrupt, albeit wavy, transition to stratified squamous epithelium, which is the colour of parchment. This wavy junction constitutes the dentate line. The dentate line is a most important landmark both morphologically and surgically, representing the site of fusion of the proctodeum and post-allantoic gut, and being the site of the crypts of Morgagni (synonym: anal crypts, sinuses). The latter are small pockets between the inferior extremities of the columns of Morgagni through which anal ducts that communicate with deeper placed anal glands open into the anal lumen. The squamous epithelium lining the lower anal canal is thin and shiny and is known as the anoderm; it differs from the true skin in that it has no epidermal appendages, i.e. hair and sweat glands. At the dentate line, the anoderm is attached more firmly to deeper structures. The mucosa and submucosa above the dentate line is uneven and thrown into folds, the so-called anal
cushions. There are variations in the numbers and positions of these cushions, but there are usually three, corresponding to those seen in later life. These are described classically as occupying the left lateral, right posterior and right anterior positions, and they continue proximally as the primary rectal foldings. Secondary foldings (the rectal columns of Morgagni) lie both over and between the primary folds. This area is the caudal limit of the so-called epithelial transitional zone, below which the stratified squamous epithelium is richly innervated by sensory nerve endings serving several modalities including touch, pain and temperature. The bulk of the anal cushions themselves, situated in the upper part of the anal canal, receive only visceral afferent innervation and, although there is perception of stretching, sensitivity to noxious stimuli is much more blunted than distally.

Between the epithelial layer and the internal sphincter lies the submucosa, consisting of vascular, muscular and connective tissue supportive elements. From the longitudinal muscle, medial extensions cross the internal anal sphincter and form part of the supporting meshwork of the submucosa, blending with the true submucosal smooth muscle layer and thereby supporting the mucosa itself. Parks described the increased density of fibres that insert into the mucosa of the anal crypts at the level of the dentate line, termed the 'mucosal suspensory ligament'. One feature of this structure is that it separates the superior (portal) and inferior (systemic) haemorrhoidal plexuses, another that the mucosa is more firmly tethered to underlying tissues at this level than above. It is important to appreciate that the meshwork of supporting tissues (muscle fibres and connective tissue) within the subepithelial space is intimately linked to deeper structures within the anal sphincter complex, including the internal sphincter, longitudinal muscle layer and external anal sphincter, and indeed structures beyond the sphincter complex. With age, the smooth muscle component of this mesh is reduced and muscle fibres are gradually replaced with fibroelastic connective tissue, which in turn becomes fragmented.

**Blood supply**

In addition to the meshwork support of the lining of the anal canal, the subepithelial space contains venous dilatations supported by the same fibroelastic connective tissue and smooth muscle scaffolding. Debate has centred on the nature of the vascular component of haemorrhoids, but the seminal anatomical studies of Thomson have clarified this issue. Venous dilatations are seen in the submucosa both above and below the level of the dentate line; they are much more numerous above, although tend to be larger below. The historical description of the blood supply to the upper anal canal as constant, with bifurcation of the main trunk of the superior rectal artery into right and left branches and with subsequent division of the former into anterior and posterior divisions thereby determining the sites of haemorrhoids around the anal circumference, was questioned by Thomson. He demonstrated that the divisions of the superior rectal artery were not constant and that, furthermore, the anal submucosa in a proportion of his specimens received a blood supply from the middle and inferior rectal arteries. He was also able to show the presence of free communications between tributaries of the superior, middle and inferior rectal veins, as well as tiny direct arteriovenous communications with the submucosal venous dilatations. These communications have been shown both histologically and radiologically, and the oxygen tension of the blood contained within the venous dilatations (as well as the colour) is more arterial than venous.

**Venous drainage**

The anal veins are distributed in a similar fashion to the arterial supply. The upper half of the anal canal is drained by the superior rectal veins, tributaries of the inferior mesenteric vein and thus the portomesenteric venous system, and the middle rectal veins, which drain into the internal iliac veins. The inferior rectal veins drain the lower half of the anal canal and the subcutaneous perianal plexus of veins: they eventually join the internal iliac vein on each side.

**Lymphatic drainage**

Lymph from the upper half of the anal canal flows upwards to drain into the postrectal lymph nodes and from there goes to the para-aortic nodes via the inferior mesenteric chain. Lymph from the lower half of the anal canal drains on each side first into the superficial and then into the deep inguinal group of lymph glands. However, if the normal flow is blocked, e.g. by tumour, the lymph can be diverted into the alternative route (Summary box 73.1).

---

**Summary box 73.1**

**Anal canal anatomy**

- The internal sphincter is composed of circular, non-striated involuntary muscle supplied by autonomic nerves
- The external sphincter is composed of striated voluntary muscle supplied by the pudendal nerve
- Extensions from the longitudinal muscle layer support the sphincter complex
- The space between sphincters is known as the intersphincteric plane
- The superior part of the external sphincter fuses with the puborectalis muscle, which is essential for maintaining the anorectal angle, necessary for continence
- The lower part of the anal canal is lined by sensitive squamous epithelium
- Blood supply to the anal canal is via superior, middle and inferior rectal vessels
- Lymphatic drainage of the lower half of the anal canal goes to inguinal lymph nodes

**The anal glands**

Anal glands (which are not vestigial remnants of sexual scent glands) may be found in the submucosa and intersphincteric space (Figure 73.4), and normally number between 0 and 10 in an individual. They drain via ducts into the anal sinuses at the level of the dentate line. Not all sinuses have a duct draining into them and, occasionally, more than one gland can discharge into the same sinus. Their function is unknown, although they secrete mucin (distinct from that secreted by the rectal epithelium).
Examination of the anus

Careful clinical examination will be diagnostic in the vast majority of patients complaining of anal symptoms, but it requires a relaxed patient who is informed of what the examination will entail, a private environment, a chaperone (for the security of both parties) and good light. Most commonly, the patient is examined in the left lateral (Sims) position with the buttocks overlying the edge of the examination couch and with the axis of the torso crossing, rather than parallel with, the edge of the couch. Alternatively, in younger patients, the prone jackknife or knee–elbow positions may be used (Figure 73.5). The examining couch should be of sufficient height to allow easy inspection and access for any necessary manoeuvres. A protective glove should be worn.

Inspection

The buttocks are gently parted to allow inspection of the anus and perineum: the presence of any skin lesions and whether they are confined to the perineum or evident elsewhere on general examination, e.g. psoriasis, lichen planus, or on genital examination, e.g. warts, candidiasis, lichen sclerosus et atrophicus, the vesicles of herpes simplex virus (HSV); evidence of anal leakage; whether the anus is closed or patulous; and the position of the anus and perineum at rest and on bearing down (the latter may reveal prolapse of haemorrhoids or even the rectum). Pain on parting the buttocks, perhaps together with the presence of a sentinel tag, may indicate the presence of an underlying fissure, but may also prompt the need for examination under anaesthesia to exclude more suspicious pathology, for example squamous cell carcinoma of the anal canal.

Digital examination with the index finger

With an adequately lubricated index finger, the soft tissues around the anus are palpated for induration, tenderness and subcutaneous lesions. The index finger is then introduced gently into the anal canal along its posterior aspect. At the apex of the canal, the sling of puborectalis is felt posteriorly; suprapleuristor induration feels bony hard and is more easily appreciated if unilateral. The posterior surface of the prostate gland with its median sulcus can be palpated anteriorly in male patients; in female patients, the uterine cervix can be palpated. The presence of any distal intrarectal, intra-anal or extraluminal mass is recorded. Sphincter length, resting tone and voluntary squeeze
are assessed. On withdrawal, the examining finger is inspected for the presence of mucus, blood or pus, and to identify stool colour.

**Proctoscopy**

Proctoscopy (Figure 73.6), performed with the patient in the same position, allows a detailed inspection of the distal rectum and anal canal. Minor procedures can also be carried out through this instrument, e.g. treatment of haemorrhoids by injection or banding (see below Management under Haemorrhoids) and biopsy. Asking the patient to bear down on slow withdrawal of the proctoscope may reveal a descending intussusception.

**Sigmoidoscopy**

Although sigmoidoscopy (see Chapter 72) is strictly an examination of the rectum, it should always be carried out even when an anal lesion has been confirmed. Rectal pathology, e.g. colitis or carcinoma, is frequently associated with an anal lesion, e.g. fissure or haemorrhoids. Not infrequently, rectal pathology is found that is independent of the anal lesion and which requires treatment (Summary box 73.2).

---

**Summary box 73.2**

**Examination of anal canal**

- A rectal examination is essential for any patient with ano-rectal and/or bowel symptoms – ‘If you don’t put your finger in, you might put your foot in it’
- A proctosigmoidoscopy is essential in any patient with bowel symptoms, and particularly if there is rectal bleeding

**PHYSIOLOGICAL ASPECTS OF THE ANAL SPHINCTERS AND PELVIC FLOOR, AND SPECIAL INVESTIGATIONS**

Anal continence and defaecation are highly complex processes that necessitate the structural and functional integrity of the cerebral, autonomic and enteric nervous systems, the gastrointestinal tract (especially the rectum) and the pelvic floor and anal sphincter complex, any of which may be compromised and lead to disturbances of function of varying severity. The sphincter mechanism provides the ultimate barrier to leakage and its integrity can be assessed fairly simply and objectively in the physiology laboratory (Swash and Henry). Perineal position and degree of descent on straining (markers of pelvic floor and pudendal nerve function) can be quantified, and functional anal canal length, resting tone (reflective predominantly of internal sphincter activity) and squeeze increment (reflective of external sphincter function) can be measured by a variety of simple manometric techniques (Figure 73.7). The structural integrity of the sphincters can be visualised with endoluminal ultrasound (Figure 73.8), and neuromuscular function can be measured by assessment of conduction velocity along the pudendal nerve on each side, or, more painfully, by needle electromyogram (EMG) studies (Figures 73.9 and 73.10). In the elderly especially, but also in younger patients, disorders relating to rectal sensorimotor dysfunction can lead to ‘overflow’ of rectal contents through what may be an otherwise normal sphincter. The dynamics of defaecation can also be assessed radiologically by evacuation proctography, in which radio-opaque pseudo-stool is inserted into the rectum and the patient asked to rest, squeeze and then bear down to evacuate the rectal contents under real-time imag-

much more expensive modality of dynamic magnetic resonance proctography has become more widespread, although studies in which the subject is asked to evacuate in the supine position may be less physiological than those in which the subject adopts a sitting position within an open magnet. Results of all physiological and imaging tests have to be compared with a robust normal range and within the context of the patient’s symptoms, and are used to guide rational rather than empirical treatment strategies.

**CONGENITAL ABNORMALITIES**

Early in embryonic life there is a common chamber – the cloaca – into which the hind gut and the allantois open. This endoderm-lined chamber is separated from the surface ectoderm of the embryo by the cloacal membrane. The cloaca becomes divided into two parts, dorsal (rectum) and ventral (urogenital sinus), by the downgrowth of a septum. The dorsal part of the cloacal membrane, known as the anal membrane, is thus composed of an outer layer of ectoderm and an inner layer of endoderm. Resorption of this anal membrane by the 8th week of embryonic life creates the anal canal.

**Imperforate anus**

Imperforate anus (see Chapter 8) (strictly, it should be anal ‘agenesis’ or ‘atresia’) has historically been divided into two main groups – high and low – depending on the level of termination of the rectum in relation to the pelvic floor. Treatment and prognosis are influenced by any associated abnormalities of the sacrum and genitourinary systems. In both sexes, low defects embrace rectoperineal fistula (Figure 73.12), covered anus and anal membrane. The most frequent defect in boys with imperforate anus is one in which the distal rectum is sited within the puborectalis sling, but terminates as a fistula into the bulb of the urethra (Figure 73.13) (see also Chapter 8, Figure 6.32) or prostatic urethra above the main anal sphincter complex. Boys with a fistula into the bladder neck (a high defect) have the poorest prognosis because of the underdevelopment of the sacrum and pelvic and anal musculature. The most common defect in girls is a rectovestibular fistula, in which the fistula opens into the posterior vestibule (not the vagina) (Figure 73.12). The finding of a single perineal orifice indicates a persistent cloaca in which the rectum, vagina and urinary tract form a confluence (Figure 73.13); the longer the common channel, the greater the likelihood of more complex defects, including vaginal and uterine septation, duplication or atresia. An anterior anus, although not imperforate, is not fully located within the sphincter mechanism and is regarded as part of the spectrum of anorectal malformations (Figure 73.12).

**Clinical management**

Careful perineal examination will usually provide the most important clues about the neonate’s type of malformation. The presence of meconium on the perineum indicates a low defect and meconium in the urine is evidence of a urinary tract fistula. During the first 24 hours, the baby should receive intravenous fluids and antibiotics, and should be evaluated for associated congenital anomalies. By 24 hours, the distal limit of air within the rectum, seen on a lateral prone radiograph, indicates the distance between the rectal stump and perineum (Figure 73.14).

**Treatment**

Low anomalies with a perineal fistula can be treated by an anoplasty. More complex malformations require early colostomy, with definitive repair performed several months later. This may
Congenital abnormalities

involve posterior sagittal anorectoplasty (PSARP, Pena) with or without transabdominal mobilisation of the left colon and division of any communication with the urinary tract. In girls with a cloaca and long common channel, urinary and vaginal reconstruction is also required. Postoperatively, a programme of anal dilatation is instituted, and any residual colostomy is closed at a later date. Ultimate bowel function (voluntary bowel movements, continence, constipation) is related to the type of anorectal abnormality and the presence of associated defects, especially sacral (Summary box 73.3).

**Summary box 73.3**

**Imperforate anus**

- A rare congenital disorder
- Classified as being high or low depending on the site of the rectal termination in relation to the pelvic floor
- Low defects: relatively easy to correct, but prone to constipation
- High defects: more difficult to correct and prone to faecal incontinence

Post-anal dermoid

The space in front of the lower part of the sacrum and coccyx may be occupied by a soft, cystic swelling – a post-anal dermoid cyst. Hidden in the hollow of the sacrum, it is unlikely to be discovered unless a sinus communicating with the exterior is present or it develops as a result of inflammation. Such a cyst usually remains asymptomatic until adult life, when it is prone to becoming infected. Exceptionally, because of its size, it gives rise to difficulty in defaecation. The cyst is easily palpable on rectal examination.

**Differential diagnosis**

Especially in a child, an anterior sacral meningocele must be excluded. This enlarges when the child cries and is frequently associated with paralysis of the lower limbs and incontinence. When a discharging sinus is present, a post-anal dermoid will probably be mistaken for a pilonidal sinus or even an anal fistula. Pressure over the sacrococcygeal region with a finger in the...
rectum may cause a flow of sebaceous material, and injection of contrast media followed by radiography reveals a bottle-necked cyst in front of the coccyx.

**Treatment**

Treatment involves complete excision of the cyst and, if present, the sinus. In the case of large cysts, it is necessary to remove the coccyx to gain access. The coccyx should also be removed en bloc in any child with a presacral dermoid because of the risk of sacrococcygeal teratoma.

**Post-anal dimple**

A post-anal dimple (synonym: fovea coccygea) is a dimple in the skin beneath the tip of the coccyx, sometimes amounting to a short blind pit. It is noticed from time to time in the course of a clinical examination and is of no consequence.

**Pilonidal sinus**

The term ‘pilonidal sinus’ describes a condition found in the natal cleft overlying the coccyx, consisting of one or more, usually non-infected, midline openings, which communicate with a fibrous track lined by granulation tissue and containing hair lying loosely within the lumen. A common affliction among the military, it has been referred to as ‘jeep disease’.

**Aetiology and pathology**

Although acquired theories of development are better accepted than the more historical congenital theories, exact mechanisms of development are speculative. Evidence that supports the acquired theory of origin of pilonidal sinuses can be summarised as follows:

- Intertidigital pilonidal sinus is an occupational disease of hairdressers, the hair within the interdigital cleft or clefs being from the customers. Pilonidal sinuses of the axilla and umbilicus have also been reported.

- The age incidence of the appearance of pilonidal sinus (82 per cent occur between the ages of 20 and 29 years) is at variance with the age of onset of congenital lesions.

- Hair follicles have almost never been demonstrated in the walls of the sinus.

- The hairs projecting from the sinus are dead hairs, with their pointed ends directed towards the blind end of the sinus.

- The disease mostly affects men, in particular hairy men.

- Recurrence is common, even though adequate excision of the track is carried out.

It is thought that the combination of buttoc k friction and shearing forces in that area allows shed hair or broken hairs which have collected there to drill through the midline skin, or that infection in relation to a hair follicle allows hair to enter the skin by the suction created by movement of the buttocks, so creating a subcutaneous, chronically infected, midline track. From this primary sinus, secondary tracks may spread laterally, which may emerge at the skin as granulation tissue-lined, discharging openings. Usually, but not invariably (when diagnosis may be confused with anal fistula or hidradenitis suppurativa), the sinus runs cephalad. Carcinoma arising in chronic pilonidal disease has been described, but is exceedingly rare.

**Clinical features**

The condition is seen much more frequently in men than in women, usually after puberty and before the fourth decade of life, and is characteristically seen in dark-haired individuals rather than those with softer blond hair (Oldham). Patients complain of intermittent pain, swelling and discharge at the base of the spine, but little in the way of constitutional symptoms. There is often a history of repeated abscesses that have burst spontaneously or which have been incised, usually away from the midline. The primary sinus may have one or many openings, all of which are strictly in the midline between the level of the sacrococcygeal joint and the tip of the coccyx.

**Conservative treatment**

As the natural history of the condition is usually one of regression, in those whose symptoms are relatively minor, simple cleaning out of the tracks and removal of all hair, with regular shaving of the area and strict hygiene, may be recommended.

**Treatment of an acute exacerbation (abscess)**

If rest, baths, local antiseptic dressings and the administration of a broad-spectrum antibiotic fail to bring about resolution, the abscess should be drained through a small longitudinal incision made over the abscess and off the midline, with thorough curettage of granulation tissue and hair. This procedure may or may not be associated with complete resolution.

**Surgical treatment of chronic pilonidal disease**

The multitude of surgical procedures advocated to eradicate pilonidal disease, combined with the lack of prospective trials, attests to the lack of overall superiority of one method over the others. Time spent off work and perceived recurrence rates, but more usually surgeon preference, influence the choice of method, which includes the laying open of all tracks with or without marsupialisation, the excision of all tracks with or without primary closure, and the excision of all tracks and then closure by some other means designed to avoid a midline wound (Z-plasty, Karydakis procedure (Figure 73.15)). Bascom’s procedure involves an incision lateral to the midline to gain access to the sinus cavity, which is rid of hair and granulation tissue (Figure 73.16), and excision and closure of the midline pits (Figure 73.17). The lateral wound is left open (Figure 73.18). Irrespective of procedure, postoperative wound care is important and centres around elimination of hair (ingrown, local or other) from the wound.

**Recurrent pilonidal sinus**

Three possibilities account for this disappointment:

- part of the sinus complex has been overlooked at the primary operation;
- new hairs enter the skin or the scar;
- there is persistence of a midline wound caused by shearing forces and scarring; in this situation, revisional surgery may include re-excision followed by wound closure and

obliteration of the natal cleft either by myocutaneous rotational buttock flap or cleft closure (Bascom).

ANAL INCONTINENCE

Aetiology
As continence is dependent upon the structural and functional integrity of both the neurological pathways and the gastrointestinal tract, the risk factors for anal incontinence are many (Summary box 73.4). Patients complaining of the involuntary loss of rectal contents require a comprehensive assessment of the nature and severity of symptoms; past history, especially of gastrointestinal disease, neurological conditions, obstetric events and anal surgery; and careful clinical examination (in the elderly, incontinence is often one of overflow secondary to rectal impaction, and proctitis may lead to such an irritable rectum that even the strongest sphincter is occasionally overwhelmed). A combination of history and examination will usually be diagnostic, but special investigations are then usually required to clarify the exact cause, including exclusion of an underlying malignancy, and to direct management.

Sphincteric causes of incontinence may be classified as structural, in which there is disruption (or atrophy) of part of the sphincter muscles, neuropathic (previously termed idiopathic), in which the nerve supply to the sphincters is damaged, usually by chronic straining or complicated vaginal delivery (prolonged second stage), or a combination of the two. The most common causes of sphincteric disruption are obstetric damage, anal surgery (following haemorrhoidectomy, dilatation or sphincterotomy for anal fissure, and fistulotomy for anal fistula) and trauma (including anal intercourse, forced or otherwise).
In general, conservative measures to reduce symptoms are employed initially. These may be in the form of stool bulking or constipating agents, nurse-led bowel retraining including specific biofeedback programmes, or anal plugs, which expand within and thus seal the anal canal. Failure of such measures and severity of symptoms may result in selection for surgery.

**Operations to reunite divided sphincter muscles**

In situations in which there is a discrete disruption of the sphincters, the ends of the divided muscle are found and reunited by a double overlap repair (Figure 73.19).

**Operations to reef the external sphincter and puborectalis muscle**

If the sphincter muscles are stretched and patulous (as they often are in old age and in cases of rectal prolapse) they may be tightened by a post-anal repair, which, through the use of darns of absorbable material to narrow down and plicate the external sphincter and the puborectalis sling (Figure 73.20), aims to recreate the anorectal angle and to restore length to the anal canal and strength to the anal sphincter. The approach is usually through the intersphincteric plane. The operation is now much less popular because long-term outcomes have been reported as poor.

**Operations to augment the anal sphincters**

If the degree of sphincter disruption or weakness is such that restoration of function cannot be achieved by direct means, the sphincter can be augmented by using muscle transposed from nearby (gluteus maximus or gracilis) or by using an artificial

Figure 73.19 Direct sphincter repair in which (a) the sphincter defect is excised and (b) the remaining muscle is overlapped. Redrawn with permission from Mann CV, Glass RE. *Surgical treatment of anal incontinence*. New York: Springer, 1991.
Anal incontinence

Sphincter. Transposition of the gracilis muscle around the anal canal is followed by electrical stimulation, with conversion from a fast-twitch to a less fatiguable slow-twitch muscle by an implanted pacemaker (Williams) (Figure 73.21). Because of its magnitude, this technique is performed only in highly selected and motivated patients, most of whom have had more conventional treatment that has failed to cure their incontinence; it is effective in approximately 60 per cent of patients in the long term. A simpler means of augmenting the sphincter, developed initially for urinary incontinence, is the placement of an inflatable silastic cuff around the anal canal. When evacuation is required, the cuff is deflated by squeezing a small balloon positioned in the scrotum or labia, the balloon being attached to a subcutaneous reservoir (Figure 73.22). However, because this device is a foreign body that exerts pressure on the bowel wall, erosion and infection have been found to be common problems. To reduce the risk of septic complications the operation should be covered by antibiotics active against both aerobic and anaerobic organisms. Paradoxically, all of these methods used to treat incontinence may be associated with difficulties in rectal evacuation.

More recently, again as a result of its use in urinary incontinence, sacral nerve stimulation has been used to treat fecal incontinence, with encouraging short- and medium-term results.

Figure 73.20 Post-anal repair in which (a) the sphincter muscle is plicated posterior to the anal canal, thus restoring the anorectal angle. (b) The completed repair. Redrawn with permission from Mann CV, Glass RE. Surgical treatment of anal incontinence. New York: Springer, 1991.

Figure 73.22 Artificial bowel sphincter. A cuff is placed around the anal canal. An inflatable pump control assembly is placed in the scrotum and the balloon reservoir is placed under the symphysis pubis.
Rather than any direct action on sphincter strength, this technique appears to work by sensorimotor neurophysiological modulation of the hindgut through electrical stimulation of the sacral nerve roots via a needle positioned through one of the posterior sacral foramina (Figure 73.23). A potential advantage of this technique is its relatively non-invasive nature, as well as the fact that its effects can be tested by temporary stimulation using an external stimulator before the expensive permanent pacemaker is implanted. A much cheaper and less invasive novel technique to treat faecal incontinence, again mediated through neuromodulation is percutaneous posterior tibial nerve stimulation (PTNS) whereby the tibial nerve at the ankle is electrically stimulated once per week for several minutes. The course of treatment is usually for 12 weeks and is administered on an outpatient basis. Results from prospective comparative studies are eagerly awaited.

For some patients, and in those in whom quality of life remains poor despite attempts at restoring continence, a permanent stoma can provide relief from a condition which is both disabling and socially isolating.

### ANAL FISSURE

#### Definition

An anal fissure (synonym: fissure-in-ano) is a longitudinal split in the anoderm of the distal anal canal (Figure 73.24), which extends from the anal verge proximally towards, but not beyond, the dentate line.

#### Aetiology

The cause of an anal fissure, and particularly the reason why the posterior midline is so frequently affected, is not completely understood. Classically, acute anal fissures arise from the trauma caused by the strained evacuation of a hard stool or, less commonly, from the repeated passage of diarrhoea. The location in the posterior midline perhaps relates to the exaggerated shearing forces acting at that site at defaecation, combined with a less elastic anoderm endowed with an increased density of longitudinal muscle extensions in that region of the anal circumference. Anterior anal fissure is much more common in women and may arise following vaginal delivery. Perpetuation and chronicity may result from repeated trauma, anal hypertonicity and vascular insufficiency, either secondary to increased sphincter tone or because the posterior commissure is less well perfused than the remainder of the anal circumference.

#### Clinical features

Simple epithelial splits, because of their location involving the exquisitely sensitive anoderm, acute anal fissures are characterised by severe anal pain associated with defaecation. This usually resolves spontaneously after a variable time only to recur at the next evacuation, as well as the passage of fresh blood, normally noticed on the tissue after wiping. Chronic fissures are characterised by a hypertrophied anal papilla internally and a sentinel tag externally (both consequent upon attempts at healing and breakdown), between which lies the slightly indurated anal ulcer overlooking the fibres of the internal sphincter. When chronic, patients may also complain of itching secondary to irritation from the sentinel tag, discharge from the ulcer or discharge from an associated intersphincteric fistula, which has arisen through infection penetrating via the fissure base. Although most sufferers are young adults, the condition can affect any age, from infants to the elderly. Men and women are affected equally. Anterior fissures account for about 10 per cent of those encountered in women, but only 1 per cent in men. A fissure sited elsewhere around the anal circumference or with atypical features should raise the suspicion of a specific aetiology, and failure of adequate examination in the clinic should prompt early examination under anaesthesia, with biopsy and culture to exclude Crohn’s disease, tuberculosis, sexually transmitted or human immunodeficiency virus (HIV)-related ulcers (syphilis, Chlamydia, chancroid, lymphogranuloma venereum, HSV, cytomegalovirus, Kaposi’s sarcoma, B-cell lymphoma) and squamous cell carcinoma (Summary box 73.5).
Summary box 73.5

**Anal fissure**
- Acute or chronic
- Ischaemic ulcer in the midline of the anal canal
- Ectopic site suggests a more sinister cause
- Symptoms:
  - Pain on defaecation
  - Bright-red bleeding
  - Mucous discharge
  - Constipation

**Treatment**
After confirmation of the diagnosis in the clinic or under anaesthesia, with exclusion of secondary causes of anal ulceration, conservative management should result in the healing of almost all acute and the majority of chronic fissures. Emphasis must be placed on normalisation of bowel habits such that the passage of stool is less traumatic. The addition of fibre to the diet to bulk up the stool, stool softeners and adequate water intake are simple and helpful measures. Warm baths and topical local anaesthetic agents relieve pain; however, providing patients with anal dilators is usually associated with low compliance and consequently little effect. The mainstay of current conservative management is the topical application of pharmacological agents that relax the internal sphincter, most commonly nitric oxide donors (Scbolefield); by reducing spasm, pain is relieved, and increased vascular perfusion promotes healing. Such agents include glyceryl trinitrate (GTN) 0.2 per cent applied four times per day to the anal margin (although this may cause headaches) and diltiazem 2 per cent applied twice daily.

**Operative measures**
Historically, under regional or general anaesthesia, forceful manual (four- or eight-digit) sphincter dilatation was used to reduce sphincter tone; however, this was achieved in an uncontrolled fashion with potential disruption at multiple sites of the internal (and even external) sphincter. The risk of incontinence following this procedure has now made it unpopular, although more conservative controlled stretching is still practised in young men with very high sphincter tone.

Fissure healing can also be achieved by a posterior division of the exposed fibres of the internal sphincter in the fissure base, but this is associated with prolonged healing, as well as passive anal leakage thought mainly to be due to the resulting keyhole gutter deformity; however, it may be indicated if there is an associated intersphincteric fistula.

**Lateral anal sphincterotomy**
In this operation, the internal sphincter is divided away from the fissure itself – usually either in the right or the left lateral positions (Notaras). The procedure can be carried out using an open or a closed method, under local, regional or general anaesthesia, and with the patient in the lithotomy or prone jackknife position. The distal internal sphincter is palpated with a bivalved speculum at the intersphincteric groove. In the closed method, a small longitudinal incision is made over this, and the submucosal and intersphincteric planes are carefully developed to allow precise division of the internal sphincter with a knife or scissors to the level of the apex of the fissure; the wound is then closed with absorbable sutures. Alternatively, either plane can be entered using a scalpel (No. 11 blade), with the blade advanced parallel to the sphincter and then rotated such that the sharp edge faces the internal sphincter, which can then be divided along its distal third. Pressure should be applied to the wound for a few minutes to prevent haematoma formation. In the open technique, the anoderm overlying the distal internal sphincter is divided longitudinally to expose the sphincter, which is divided, and the wound is closed with absorbable sutures. Although the fissure needs no specific attention, problematic papillae and external tags can be excised concomitantly.

Early complications of sphincterotomy include haemorrhage, haematoma, bruising, perianal abscess and fistula. Despite low recurrence rates, the most important complication is incontinence of a variable nature and severity, which may affect up to 30 per cent of patients, particularly women, who have weaker, shorter sphincter complexes and in whom there may already have been covert sphincter compromise incurred by childbirth.

**Anal advancement flap**
The recognition of the risk to continence following internal sphincterotomy has led some to advocate a different approach, especially in women and those with normal or low resting anal pressures, developed from the treatment of anal stenosis. After excision of the edges of the fissure and, if necessary, its base overlying the internal sphincter, an inverted house-shaped flap of perianal skin is carefully mobilised on its blood supply and advanced without tension to cover the fissure, and then sutured with interrupted absorbable sutures (Figure 73.25). The patient is maintained on stool softeners and bulking agents postoperatively, and usually also on topical sphincter relaxants; minor breakdown of one anastomotic edge does not herald ultimate failure (Summary box 73.6). The technique appears to work irrespective of sphincter hypertonicity or patient gender.

John Howard Scoblefield, contemporary, Professor of Surgery, The University of Nottingham, Nottingham, UK.
Mitchell James Notaras, surgeon, Barnet General Hospital, Barnet, UK.

**Figure 73.25** Mobilised skin flap prior to suturing intra-anally over the debrided and freshened posterior fissure base.
Hypertrophied anal papilla

Anal papillae occur at the dentate line and are remnants of the ectodermal membrane that separated the hindgut from the proctodaeum. As these papillae are present in 60 per cent of patients examined proctologically, they should be regarded as normal structures. Anal papillae can become elongated, as they frequently do in the presence of an anal fissure. Occasionally, an elongated anal papilla may be the cause of pruritus. An elongated anal papilla associated with pain and/or bleeding at defaecation is sometimes encountered in infancy. Haemorrhage into a hypertrophied anal papilla can cause sudden rectal pain. A prolapsed papilla may become nipped by contraction of the sphincter mechanism after defaecation. Occasionally, a red oedematous papilla is encountered, with local pain and a purulent discharge from the associated crypt. This condition of ‘cryptitis’ may be cured by laying open the mouth of the infected anal gland and excising the papilla. Troublesome papillae may be simply excised.

Proctalgia fugax

This problem is characterised by attacks of severe pain arising in the rectum, recurring at irregular intervals and apparently unrelated to organic disease. The pain is described as cramp-like, often occurs when the patient is in bed at night, usually lasts only for a few minutes and disappears spontaneously. It may follow straining at stool, sudden explosive bowel action or ejaculation. It seems to occur more commonly in patients suffering from anxiety or undue stress, and it is also said to afflict young doctors. The pain may be unbearable – it is possibly caused by segmental cramp in the pubococcygeus muscle. It is unpleasant and incurable, but is fortunately harmless and gradually subsides. If patients have frequent attacks, they may benefit from amitryptiline. Salbutamol inhalers have been suggested as treatment for acute attacks. A more chronic form of the disease has been termed the ‘levator syndrome’ and can be associated with severe evacuatory dysfunction. Biofeedback techniques have been used to help such patients; in the past, some surgeons tried severing the puborectalis muscle, but this can cause incontinence and should never be carried out.

HAEMORRHOIDS

The prevalence of haemorrhoids when patients are assessed proctoscopically far outweighs the prevalence of symptoms, and the term should only be used when patients have symptoms referable to them. Occasionally, patients with portal hypertension develop rectal varices, but these should not be confused with haemorrhoids as the consequences may be disastrous. Internal haemorrhoids (Greek: haima, blood; rhoos, flowing; synonym: piles, Latin: pila, a ball) are symptomatic anal cushions and characteristically lie in the 3, 7 and 11 o’clock positions (with the patient in the lithotomy position). In addition, haemorrhoids may be observed between the main pile masses, in which case they are internal haemorrhoids at the secondary position. External haemorrhoids relate to venous channels of the inferior haemorrhoidal plexus deep in the skin surrounding the anal verge and are not true haemorrhoids; they are usually only recognised as a result of a complication, which is most typically a painful solitary acute thrombosis. External haemorrhoids associated with internal haemorrhoids (‘interoexternal piles’) result from progression of the latter to involve both haemorrhoidal plexuses and are best thought of as being external extensions of internal haemorrhoids. Secondary internal haemorrhoids arise as a result of a specific condition, although the mechanisms involved may be the same as those involved in the formation of primary internal haemorrhoids. The most important cause, albeit relatively uncommon, is carcinoma of the anorectum (Figure 73.26), but there are many other causes, which may be categorised as follows:

- local, e.g. anorectal deformity, hypotonic anal sphincter;
- abdominal, e.g. ascites;
- pelvic, e.g. gravid uterus, uterine neoplasm (fibroid, carcinoma of the uterus or cervix), ovarian neoplasm, bladder carcinoma;
- neurological, e.g. paraplegia, multiple sclerosis.

Figure 73.26 Carcinoma of the rectum associated with haemorrhoids, a not infrequent diagnostic pitfall.
Primary internal haemorrhoids

Theories of development

Portal hypertension and varicose veins

Misconceptions concerning the vascular anatomy of the anal canal (specifically the lack of appreciation of communications between portal and systemic systems and the ‘normality’ of venous dilatations) led to theories of development of primary internal haemorrhoids that lasted for several centuries. Man’s upright posture (we know little about haemorrhoidal problems in animals), lack of valves in the portal venous system and raised abdominal pressure were thought to contribute to the development of anal varicosities. If raised portal venous pressure were indeed the cause, one would expect a high incidence in subjects suffering from portal hypertension; however, although such patients have a higher incidence of anorectal varices, these are a separate anatomical and clinical entity from haemorrhoids, which are seen no more frequently than in those without cirrhosis, portal hypertension and oesophageal varices.

Other vascular causes

Historically, some considered haemorrhoids to be haemangiomatous or to result from changes in the erectile tissue that forms part of the continence mechanism, such as hyperplasia of the ‘corpus cavernosum recti’.

Infection

Repeated infection of the anal lining, secondary to trauma at defaecation, has been postulated as a cause of weakening and erosion of the walls of the veins of the submucosa. This hypothesis is difficult to accept, as one of the truly incredible properties of the anal canal is its resistance to infection, as well as the ability of its mucosa to heal after surgical intervention despite the torrent of micro-organisms passing over it.

Diet and stool consistency

Much emphasis has been placed on the role of constipation in the development of haemorrhoids and, indeed, much of the management of sufferers involves attempts to ‘normalise’ bowel habits. A fibre-deficient diet results in a prolonged gut transit time, which is associated with the passage of smaller, harder stools that require more straining to expel. The presence of a hard faecal mass in the rectum could obstruct venous return, resulting in engorgement of the anal veins with the act of straining at stool or sitting for prolonged periods on the lavatory with a relaxed perineum, causing a disturbance of vascular flow. However, the epidemiological pattern of constipation is different from that of haemorrhoidal disease and, indeed, an association has been demonstrated between haemorrhoids and diarrhoeal disorders.

Anal hypertension

The association between raised anal canal resting pressure and haemorrhoids is well known, but whether anal hypertension causes symptoms attributable to haemorrhoids or whether anal cushion hypertrophy causes anal hypertension is a subject of debate. The fact that surgical haemorrhoidectomy restores resting pressures to the normal range is not absolute evidence that the pile masses themselves are the cause of the hypertonia. It should be remembered, however, that there are a significant proportion of patients who suffer haemorrhoidal symptoms in whom the anal canal is relatively patulous, and there is mucosal prolapse, which is associated with perineal descent and pudendal neuropathy.

Ageing

In contrast to the anal cushion of early life, with age, the supporting structures show a higher proportion of collagen than muscle fibres and are fragmented and disorganised. Presumably, these changes arise over time with continued use of the anal canal for defaecation; however, similar changes are noted historically in surgically excised haemorrhoids in younger patients.

Current view

Shearing forces acting on the anus (for a variety of reasons) lead to caudal displacement of the anal cushions and mucosal trauma. With time, fragmentation of the supporting structures (a normal consequence of ageing, but perhaps accelerated in those with haemorrhoids) leads to loss of elasticity of the cushions such that they no longer retract following defaecation.

Clinical features

Bleeding, as the name haemorrhoid implies, is the principal and earliest symptom. The nature of the bleeding is characteristically separate from the motion and is seen either on the paper on wiping or as a fresh splash in the pan. Very rarely, the bleeding may be sufficient to cause anaemia. Pain is not commonly associated with the bleeding and its presence should make the clinician alert to the possibility of another diagnosis; however, pain may result from congestion of pile masses below a hypertonic sphincter. Piles associated with bleeding alone are called first-degree haemorrhoids (Summary box 73.7).

Summary box 73.7

Haemorrhoids: clinical features

- Haemorrhoids or piles are symptomatic anal cushions
- They are more common when intra-abdominal pressure is raised, e.g. in obesity, constipation and pregnancy
- Classically, they occur in the 3, 7 and 11 o’clock positions with the patient in the lithotomy position
- Symptoms of haemorrhoids:
  - bright-red, painless bleeding
  - mucous discharge
  - prolapse
  - pain only on prolapse

Patients may complain of true ‘piles’, lumps that appear at the anal orifice during defaecation and which return spontaneously afterwards (second-degree haemorrhoids), piles that have to be replaced manually (third-degree haemorrhoids) (Figure 73.27) or piles that lie permanently outside (fourth-degree haemorrhoids). By this stage, there is often a significant cutaneous component to the pile masses, which arise through repeated congestion and oedema. In addition to the main symptoms of pain and prolapse, patients may complain of anal irritation, which may occur as a result of mucus secretion from the caudally displaced rectal mucosa, minor leakage through a now imperfect anal seal or difficulties in cleaning after defaecation because of the irregularity of the anal verge (Summary box 73.8).
Four degrees of haemorrhoids
- First degree – bleed only, no prolapse
- Second degree – prolapse, but reduce spontaneously
- Third degree – prolapse and have to be manually reduced
- Fourth degree – permanently prolapsed

Complications
Profuse haemorrhage is uncommon. The bleeding mainly occurs externally but it may continue internally after the bleeding haemorrhoid has retracted or has been returned. In these circumstances, the rectum is found to contain blood (Summary box 73.9).

Complications of haemorrhoids
- Strangulation and thrombosis (Figure 73.28)
- Ulceration
- Gangrene
- Portal pyaemia
- Fibrosis

Treatment of complications
- Strangulation, thrombosis and gangrene. In these cases, it was formerly believed that surgery would promote portal pyaemia. However, if adequate antibiotic cover is given from the start, this is not found to be so, and immediate surgery can be justified in many patients. The other risk if surgery is performed at this stage, that of postoperative stenosis, results in some surgeons reviewing the situation much later and carrying out haemorrhoidectomy only if necessary. Besides adequate pain relief, bed rest with frequent hot baths and warm or cold saline compresses with firm pressure usually cause the pile mass to shrink considerably in 3–4 days (the authors’ preference is shrinkage through external application of small bags of frozen peas). An anal dilatation technique has in the past been used as an alternative treatment to surgery for painful ‘strangulated’ haemorrhoids (Figure 73.28). However, because of the risk of incontinence this is no longer advised.

- Severe haemorrhage. The cause usually lies in a bleeding diathesis or the use of anticoagulants. If such causes are excluded, a local compress containing adrenaline solution, with an injection of morphine and blood transfusion if necessary, will usually suffice. However, after adequate blood replacement, ligation and excision of the piles may be required.

Management
Exclusion of other causes of rectal bleeding, especially colorectal malignancy, is the first priority. In the absence of a specific predisposing cause, important measures include attempts at normalising bowel and defaecatory habits: only evacuating when the natural desire to do so arises, adopting a defaecatory position to minimise straining, and the addition of stool softeners and bulking agents to ease the defaecatory act. Various proprietary creams can be inserted into the rectum from a collapsible tube fitted with a nozzle, at night and before defaecation. Suppositories are also useful.

In those with first- or second-degree piles whose symptoms are not improved by conservative measures, injection sclerotherapy (Mitchell), the submucosal injection of 5 per cent phenol in arachis oil or almond oil, may be advised. Any invasive treatment, however, must be with full agreement of the patient, who should be informed of the potential risks of such interventions. The aim is to create fibrosis, cause obliteration of the vascular channels and hitch up the anorectal mucosa.

- Fibrosis

Figure 73.28 An attack of piles. Prolapsed strangulated piles, as commonly seen, on the left. A less common mass on the right with fibrofatty covering.

Clinton Mitchell of Illinois, IL, USA was the first to use carbolic acid for injecting haemorrhoids. Itinerant irregular practitioners exploited the method.
With the awake patient in the left lateral position and under direct vision with a proctoscope, about 5 mL of sclerosant is injected into the apex of the pile pedicle (Figure 73.29) using a (now) disposable needle and syringe (Figure 73.30). The procedure is repeated for each pile and the patient reassessed after 8 weeks; if necessary, the injections are repeated. Pain upon injection means that the needle is in the wrong place and should be withdrawn. Injections that are too superficial are heralded by the rapid bulging of the mucosa, which turns white; this leads to superficial ulceration but rarely serious septic sequelae. However, injections placed too deeply can have disastrous consequences, including pelvic sepsis, prostatitis, impotence and rectovaginal fistula.

For more bulky piles, banding has been shown to be efficacious, but it is associated with more discomfort. The Barron’s banded is a commonly available device used to slip tight elastic bands onto the base of the pedicle of each haemorrhoid (Figure 73.31). The bands cause ischaemic necrosis of the piles, which slough off within 10 days; this may be associated with bleeding, about which the patient must be warned. As with sclerotherapy, three piles may be treated at one session, and the process may be repeated after several weeks if necessary. The techniques of cryotherapy (Lloyd Williams) and infrared photocoagulation (Leicester) are not often used nowadays.

**Operation**

**Indications**

The indications for haemorrhoidectomy include:
- third- and fourth-degree haemorrhoids;
- second-degree haemorrhoids that have not been cured by non-operative treatments;
- fibrosed haemorrhoids;
- interoexternal haemorrhoids when the external haemorrhoid is well defined.

If there is any doubt about the diagnosis of haemorrhoids, examination under anaesthesia and, if indicated, biopsy are necessary. The other strong indication for surgery is haemorrhoidal bleeding sufficient to cause anaemia. Beyond these, the indications summarised above are more relative than absolute, because in these situations surgery aims simply to improve symptoms and, of course, is not without risk. For instance, elderly multiparous women with hypotonic sphincters who are just continent before haemorrhoidectomy may find that the procedure results in frank incontinence, a far worse condition than that for which they originally sought help.

---

**Figure 73.29** Correct site (cross) for injecting a haemorrhoid (after WB Gabriel, London, UK).

**Figure 73.30** Gabriel’s syringe (a) has now been replaced by disposable syringes (b).

**Figure 73.31** Barron’s banding apparatus, with the appearance of a typical ‘banded’ haemorrhoid.
Technique

It is usual for the patient to have been taking stool softeners in the days before surgery and a preoperative enema to empty the rectum is administered. The procedure is usually performed under general or regional anaesthesia with the patient in the lithotomy or prone jack-knife position. The perianal skin is shaved and a formal examination performed. Haemorrhoidectomy can be performed using an open or a closed technique. The open technique is most commonly used in the UK and is known as the Milligan–Morgan operation – named after the surgeons who described it. The closed technique is the popular technique in the United States. Both involve ligation and excision of the haemorrhoid, but in the open technique the anal mucosa and skin are left open to heal by secondary intention, and in the closed technique the wound is sutured.

- **Open technique.** The anoderm and subcutaneous tissues between the pile masses may be injected with dilute adrenaline (epinephrine, 1:300,000 dilution) to reduce bleeding and aid preservation of the skin bridges left following excision. Artery forceps are applied to the skin-covered external components of the piles and traction exerted to reveal the internal components, which are also grasped by artery forceps. When held out by the assistant, these pairs of artery forceps form a triangle (Figure 73.32a). The operator takes the left lateral pair of artery forceps in the palm of the hand and places the extended forefinger in the anal canal to support the internal haemorrhoid. In this way, traction is applied to the skin of the anal margin. With scissors or cutting diathermy, a V-shaped cut is made through the skin and those fibres inserting into it around the skin-holding artery forceps. Traction by both operator and assistant, combined with careful dissection, will expose the lower border of the internal sphincter. The dissection proceeds up the anal canal, with the sides of the mucosal dissection converging towards the pile apex and with the internal sphincter visible and separate from the dissected pile (Figure 73.32b). A transfixion ligature of strong Vicryl is applied to the pedicle at this level (Figure 73.32c), the pile is excised well distal to the ligature and, after ensuring haemostasis, the ligature is cut long. Each haemorrhoid is dealt with in this manner, taking care to leave mucocutaneous bridges. If there are significant secondary haemorrhoids under these bridges, they can

---

be filleted out by scissor dissection. Haemostasis must be absolute at the end of the procedure, when a soft absorbable anal dressing is inserted. The margins of the skin wounds are trimmed so as not to leave overhanging edges (Figure 73.33). Bleeding subcutaneous arteries having been secured, the areas denuded of skin are dressed with three pieces of petroleum jelly gauze. A pad of gauze and wool and a firmly applied T-bandage complete the operation.

- **Closed technique.** The haemorrhoid is excised, together with the overlying mucosa, as illustrated in Figure 73.34a. The haemorrhoid is dissected carefully from the underlying sphincter and haemostasis is achieved. The pedicle is transfixed and ligated with 3/0 Vicryl or Dexon. Any residual small haemorrhoids should be removed by filleting them out after undermining the edges of the cut mucosa. The mucosal defect is then closed completely with a continuous suture using the same stitch that was employed to ligate the haemorrhoid pedicle. The remaining haemorrhoids are excised and ligated in a similar fashion, ensuring that there are adequate mucosal and skin bridges between each area of excision to avoid a subsequent stenosis.

With the aim of symptom relief but preservation of the anal cushions, the technique of stapled haemorrhoidopexy (Longo), which utilises a purpose-designed stapling gun (PPH, Ethicon Inc.), has recently been described. This procedure excises a strip of mucosa and submucosa (together with the vessels travelling within them) circumferentially, well above the dentate line. Activation of the gun also simultaneously repairs the cut mucosa and submucosa by stapling the edges together (Figure 73.35). This procedure is quick to perform, and controlled trials suggest that it is less painful and less traumatic than conventional haemorrhoidectomy and, at least in the short term, it seems to be equally efficacious. However, evidence is emerging that the technique is associated with higher recurrence rates than following conventional haemorrhoidectomy, and associated with more additional surgery. The patient, after counselling, may choose to accept a higher recurrence rate to take advantage of the short-term benefits, or not (Summary box 73.10).

---

**Figure 73.33** The appearance of the anus at the conclusion of the operation. (Note that to avoid stricture formation, it is necessary to ensure that a bridge of skin and mucous membrane remains between each wound.) ‘If it looks like a clover the trouble is over, if it looks like a dahlia, it is surely a failure.’ Reproduced with permission from Nicholls RJ, Dozois RR. Surgery of the colon and rectum. Edinburgh: Churchill Livingstone, 1997.

Summary box 73.10

**Treatment of haemorrhoids**
- Symptomatic – advice about defaecatory habits, stool softeners and bulking agents
- Injection of sclerosant
- Banding
- Transanal haemorrhoidal dearterialisation/
  haemorrhoidopexy
- Haemorrhoidectomy

**Transanal haemorrhoidal dearterialisation**

Transanal haemorrhoidal dearterialisation (THD) is used for the treatment of second- and third-degree haemorrhoids. Some have recently advocated transanal Doppler-guided ligation of those vessels feeding the haemorrhoidal masses, to which others have added suture ‘mucopexy’ to deal with any prolapse. Long-term outcomes are unknown, but recurrence rates for fourth-degree haemorrhoids (certainly when additional procedures are not incorporated) are high.

**Postoperative care**

In these days of economic stringencies, the patient is discharged from hospital within a day or two of the operation. In many countries, the procedure is often performed on a day-care basis. The patient is instructed to take two warm baths each day and is given a bulk laxative to take twice daily together with appropriate analgesia. There is some evidence that a 5-day course of oral metronidazole may reduce pain. Dry dressings are applied as necessary, a sterile sanitary towel usually being ideal. The patient is seen again 3–4 weeks after discharge and a rectal examination is performed. If there is evidence of stenosis, the patient is encouraged to use a dilator.

**Postoperative complications**

Postoperative complications may be early or late. Early complications include pain, which may require opiate analgesia; retention of urine, especially in men, which rarely may need relief by catheterisation; and reactionary haemorrhage, which is much more common than secondary haemorrhage. The haemorrhage may be mainly or entirely concealed, but will become evident on examining the rectum. If persistent following adequate analgesia, the patient must be taken to the operating theatre and the bleeding point secured by careful diathermy or under-running with a ligature on a needle, care being taken to avoid damage to the internal sphincter. Should a definite bleeding point not be found, the anal canal and rectum are packed.

Late postoperative complications include:

- Secondary haemorrhage. This is uncommon, occurring about the 7th or 8th day after operation. It is usually controlled by morphine but, if the haemorrhage is severe, an anaesthetic should be given and the bleeding controlled.
- Anal stricture, which must be prevented at all costs. A rectal examination at the postoperative review will indicate whether strictureting is to be expected. It may then be necessary to give a general anaesthetic and dilate the anus. After that, daily use of the dilator should give a satisfactory result.
- Anal fissures and submucous abscesses.
Incontinence, especially if there has been inadvertent damage to the underlying internal sphincter. Although uncommon, this is obviously a very serious problem that is difficult to treat (Summary box 73.11).

**Summary box 73.11**

**Complications of haemorrhoidectomy**

- **Early**
  - Pain
  - Reactionary haemorrhage
- **Late**
  - Secondary haemorrhage
  - Anal stricture
  - Anal fissure
  - Incontinence

**External haemorrhoids**

A thrombosed external haemorrhoid relates anatomically to the veins of the superficial or external haemorrhoidal plexus and is commonly termed a 'perianal haematoma'. It presents as a sudden onset, olive-shaped, painful blue subcutaneous swelling at the anal margin and is usually consequent upon straining at stool, coughing or lifting a heavy weight (Figure 73.36). The thrombosis is usually situated in a lateral region of the anal margin. If the patient presents within the first 48 hours, the clot may be evacuated under local anaesthesia. Untreated it may resolve, suppurate, fibrose and give rise to a cutaneous tag, burst and the clot extrude, or continue bleeding. In the majority of cases, resolution or fibrosis occurs. Indeed, this condition has been called 'a 5-day, painful, self-curing lesion' (Milligan).

**PRURITUS ANI**

This is intractable itching around the anus, a common and embarrassing condition. Usually, the skin is reddened and hyperkeratotic and it may become cracked and moist.

**Causes**

The causes are numerous. A useful mnemonic is ‘pus, polypus, parasites, piles, psyche’:

- **Lack of cleanliness**, excessive sweating and wearing rough or woollen underclothing.
- **An anal or perianal discharge** that renders the anus moist. The causative lesions include an anal fissure, fistula-in-ano, prolapsed internal or external haemorrhoids, genital warts and excessive ingestion of liquid paraffin. A mucous discharge is an intense pruritic agent and a polyp can be the cause.
- **A vaginal discharge**, especially caused by *Trichomonas vaginalis* infection.
- **Parasitic causes**. Threadworms should be excluded, especially in young subjects. Children suffering from threadworms should wear gloves at night, lest they scratch the perianal region and are reinfested with ova by nail biting – 'parasites lost, parasites regained'. Scabies and pediculosis pubis may infest the anal region.
- **Epidermophytosis** is a common cause, especially if the skin between the toes is also infected; microscopic and cultural examinations are essential. Half-strength Whitfield's ointment quickly gives relief and is the sheet anchor of treatment.
- **Allergy** is sometimes the cause, in which case there is likely to be a history of other allergic manifestations, such as urticaria, asthma or hay fever. Antibiotic therapy may be the precipitating factor.
- **Skin diseases** localised to the perianal skin: psoriasis, lichen planus and contact dermatitis.
- **Bacterial infection**, such as intertrigo resulting from a mixed bacterial infection. Erythrasma caused by *Corynebacterium minutissimum* is responsible for some cases and its presence is detected by ultraviolet light, which induces a pink fluorescence.
- **A psychoneurosis**. It is alleged that in a few instances neurotic individuals become so immersed in their complaint that a pain-pleasure complex develops, the pleasure being the scratching. Possibly this is true, but such a syndrome should not be assumed without firm grounds for coming to this conclusion.
- **Diabetes** can sometimes present with pruritus ani, and the urine should be tested in all patients.

**Treatment**

The cause is treated. Symptomatic treatment includes the following:

- **Hygiene measures**. Cotton wool should be substituted for toilet paper. Soap is avoided and replaced by water alone,
and the area pat-dried rather than rubbed. These measures alone, combined with wearing cotton underwear and the application of calamine lotion or zinc and castor oil, are all that is necessary to cure some cases. If there is much anal hair trapping the moisture and discharge, shaving can be very helpful.

- **Hydrocortisone.** In patients with dermatitis, and only in patients with dermatitis, the topical application of 0.5 or 1 per cent prednisolone cream is often beneficial; sometimes after discontinuation of the therapy, the pruritus is liable to return, in which case 5 per cent lidocaine hydrochloride (Xylocaine) ointment can be substituted for a time.

- **Strapping the buttocks** keeps moist opposing surfaces apart, but is not well tolerated. If the moistness originates from anal discharge, a cotton wool anal plug will seal the anal orifice.

**Operative treatment**

This may be necessary for a concomitant lesion of the anorectum that is thought to initiate or contribute to the pruritus. Otherwise, surgery is not indicated (Summary box 73.12).

### Summary box 73.12

**Pruritus ani**

- Common
- Numerous causes including skin diseases, parasites (threadworm), anal discharge, allergies, diabetes
- Treat the cause if possible
- Symptomatic treatment is the mainstay

**ANORECTAL ABSCESSES**

Acute sepsis in the region of the anus is common. A fundamental distinction that has to be made is whether the sepsis is in that area by chance (simple boil, skin appendage infection) or whether it has arisen as a consequence of the presence of the anorectum, specifically the anal glands. Overall, anorectal sepsis is more common in men than women, although infections with skin-type organisms (and thus unrelated to fistula) are evenly distributed. The cryptoglandular theory of intersphincteric anal gland infection (Parks) holds that, upon infection of a gland, pus, which travels along the path of least resistance, may spread caudally to present as a perianal abscess, laterally across the external sphincter to form an ischiorectal abscess or, rarely, superiorly above the anorectal junction to form a suprarealator intermuscular or pararectal abscess (depending on its relation to the longitudinal muscle), as well as circumferentially in any of the three planes: intersphincteric/intermuscular, ischiorectal or pararectal suprarealator (Figure 73.37). Sepsis unrelated to anal gland infection may occur at the same or at other sites (Figure 73.38), including submucosal abscess (following haemorrhoidal sclerotherapy, which usually resolve spontaneously), mucocutaneous or marginal abscess (infected haematoma), ischiorectal abscess (foreign body, trauma, deep skin-related infection) and pelvirectal suprarealator sepsis originating in pelvic disease. Underlying rectal disease, such as neoplasm and particularly Crohn’s disease, may be the cause. Similarly, patients with generalised disorders, such as diabetes and acquired immunodeficiency syndrome (AIDS), may present with an anorectal abscess; in these patients, abscesses may run an aggressive course.

**Presentation**

A perianal abscess, confined by the terminal extensions of the longitudinal muscle, is usually associated with a short (2–3 day)
History of increasingly severe, well-localised pain and a palpable tender lump at the anal margin. Examination reveals an indurated hot tender perianal swelling. Patients with infection in the larger fatty-filled ischiorectal space, in which tissue tension is much lower, usually present later, with less well-localised symptoms but more constitutional upset and fever. On examination, the affected buttock is diffusely swollen with widespread induration and deep tenderness. If sepsis is higher, deep rectal pain, fever and sometimes disturbed micturition may be the only features, with nothing evident on external examination but tender suprapubic induration palpable on digital examination above the anorectal junction.

**Differential diagnosis**

The only conditions with which an anorectal abscess is likely to be confused are abscesses connected with a pilonidal sinus, Bartholin’s gland or Cowper’s gland.

**Management**

Management of acute anorectal sepsis is primarily surgical, including careful examination under anaesthesia, sigmoidoscopy and proctoscopy, and adequate drainage of the pus. For perianal and ischiorectal sepsis (with an incidence of 60 and 30 per cent, respectively), drainage is through the perineal skin, usually through a cruciate incision over the most fluctuant point, with excision of the skin edges to deroof the abscess (Figure 73.39). Pus is sent for microbiological culture (Grace) and tissue from the wall is sent for histological appraisal to exclude specific causes. With a finger in the anorectum to avoid creation of a false opening, the cavity is carefully curetted. A gentle search may be made for an underlying fistula if the surgeon is experienced, and, if obvious, a loose draining seton may be passed; injudicious probing in the acute stage is, however, potentially dangerous and may lead to a much more difficult situation. Unless by highly experienced hands, immediate fistulotomy should not be performed. After irrigation of the cavity, the wound is lightly tucked; antibiotics are prescribed if there is surrounding cellulitis and especially in those less resistant to infection, such as diabetics. If the pus subsequently cultures skin-type organisms, there will be no underlying fistula and the patient can be reassured. If gut flora are cultured, it is likely, but not inevitable, that there is an underlying fistula.

The management of supralevator sepsis is dependent upon its exact anatomy (within or outside the rectal wall) and its origin. Sepsis originating in pelvic disease necessitates appropriate management of the underlying cause (appendiceal, gynaecological, diverticular, Crohn’s disease, malignancy), although intrarectal drainage may be apt to avoid creation of an extrasphincteric fistula. Cephalad extension of an intersphincteric fistula can be safely drained into the rectum, whereas supralevator extension of a trans-sphincteric fistula should be drained via the skin of the buttock. Rarely, a colostomy may be necessary to control severe sepsis, especially in the immunocompromised individual (Summary box 73.13).

**FISTULA-IN-ANO**

A fistula-in-ano, or anal fistula, is a chronic abnormal communication, usually lined to some degree by granulation tissue, which runs outwards from the anorectal lumen (the internal opening) to an external opening on the skin of the perineum or buttock (or rarely, in women, to the vagina). Anal fistulae may be found in association with specific conditions, such as Crohn’s disease, tuberculosis, lymphogranuloma venereum, actinomycosis, rectal duplication, foreign body and malignancy (which may also very rarely arise within a longstanding fistula), and suspicion of these should be aroused if clinical findings are unusual. However, the majority are termed non-specific, idiopathic or cryptoglandular, and intersphincteric anal gland infection is deemed central to them.

**Presentation**

For reasons that are unknown, non-specific anal fistulae are more common in men than women. The overall incidence is about nine cases per 100000 population per year in Western Europe, and those in their third, fourth and fifth decades of life are most commonly affected. Patients usually complain of intermittent purulent discharge (which may be bloody) and pain (which increases until temporary relief occurs when the pus discharges). There is often, but not invariably, a previous episode of acute anorectal sepsis that settled (incompletely) spontaneously or with antibiotics, or which was surgically drained. The passage of flatus or faeces through the external opening is suggestive of a rectal rather than an anal internal opening.

---

Figure 73.39 Incision of an ischiorectal abscess. The cavity is explored and, if septa exist, they should be broken down gently with a finger and the necrotic tissue lining the walls of the abscess removed by the finger wrapped in gauze. It is wise to biopsy the wall and send the pus for culture. Nothing further is done at this stage.

Caspar Bartholin, Secundus, 1655–1709, Professor of Medicine, Anatomy and Physics, Copenhagen, Denmark, described these glands in 1677.

William Cowper, 1660–1709, London surgeon, described these glands in 1697.

Roger Hew Grace, formerly Professor of Colorectal Surgery, The Royal Wolverhampton Hospital, Wolverhampton, UK.
Classification

The most widespread and useful classification of anal fistulae is that proposed by Parks, based on the centrality of intersphincteric anal gland sepsis (the internal opening is usually at the dentate line), which results in a primary track whose relation to the external sphincter defines the type of fistula and which influences management (Figure 73.40).

Classifications based simply on level are less practical because they mean different things to different people, although the description of a fistula as high, indicating a high risk of incontinence if laid open, or low, with a lower but still some risk to function, is often used. Similarly, ‘simple’ and ‘complex’ are commonly used adjectives – complexity may be endowed by the level at which the primary track crosses the sphincters, the presence of secondary extensions or the difficulties faced in treatment. The vast majority of fistulae are intersphincteric or trans-sphincteric.

Intersphincteric fistulae (45 per cent) do not cross the external sphincter (bar, for the purist, the most medial subcutaneous fibres running below the distal border of the internal sphincter); most commonly they run directly from the internal to the external openings across the distal internal sphincter, but may extend proximally in the intersphincteric plane to end blindly with or without an abscess, or enter the rectum at a second internal opening.

Trans-sphincteric fistulae (40 per cent) have a primary track that crosses both internal and external sphincters (the latter at a variable level) and which then passes through the ischiorectal fossa to reach the skin of the buttock. The primary track may have secondary tracks arising from it, which often reach the roof of the ischiorectal fossa, which may rarely pass through the levators to reach the pelvis and which may spread circumferentially (horseshoe). Circumferential spread of sepsis may occur in the intersphincteric and pararectal planes, as well as in the ischiorectal plane.

Suprasphincteric fistulae are very rare, are thought by some to be iatrogenic and are difficult to distinguish from high-level trans-sphincteric tracks (for which, fortunately, management strategies are similar). Extrasphincteric fistulae run without specific relation to the sphincters and usually result from pelvic disease or trauma.

Clinical assessment

A full medical (including obstetric, gastrointestinal, anal surgical and continence) history and proctosigmoidoscopy are necessary to gain information about sphincter strength and to exclude associated conditions. The key points to determine are the site of the internal opening; the site of the external opening(s); the course of the primary track; the presence of secondary extensions; and the presence of other conditions complicating the fistula. Palpable induration between external opening and anal margin suggests a relatively superficial track, whereas supralevator induration suggests a primary track above the levators or high in the roof of the ischiorectal fossa, or a high secondary extension. Intersphincteric fistulae usually have an external opening close to the anal verge. Goodsall’s rule (Figure 73.41), used to indicate the likely position of the internal opening according to the position of the external opening(s), is helpful but not infallible. The site of the internal opening may be felt as a point of induration or seen as an enlarged papilla. Probing in an awake patient is painful, unhelpful and can be dangerous. Full examination under anaesthesia should be repeated before surgical intervention. Dilute hydrogen peroxide, instilled via the external opening, is a very useful way of demonstrating the site of the internal opening; gentle use of probes (Figure 73.42) and a finger in the anorectum usually delineates primary and secondary tracks and their relations to the sphincters. Any concerns about fistula topography at clinical examination or examination under anaesthesia (more common after previous unsuccessful surgery) should prompt further investigations before surgical intervention.

Special investigations

A successful outcome after fistula surgery requires an accurate assessment of the fistula itself, the sphincter through which it passes and patient expectations (especially in terms of risk to continence). Clinical examination will give some indication

---

David Henry Goodsall, 1843–1906, surgeon, St Mark’s Hospital, London, UK.
of functional anal sphincter length, resting tone and voluntary squeeze; these may be more objectively assessed by manometry, whereas endoanal ultrasound gives useful information about sphincter integrity – the knowledge so gained may well influence surgical strategy. Endoanal ultrasound, especially with hydrogen peroxide, can also be used to delineate fistulae, although definition of sepsis outside or above the sphincters is limited by the probe’s focal range and scarring makes interpretation difficult. Nonetheless, ultrasound, which is more accurate than clinical examination, is useful to determine whether a fistula is relatively straightforward or not. Magnetic resonance imaging (MRI) is acknowledged to be the ‘gold standard’ for fistula imaging, but it is limited by availability and cost and is usually reserved for difficult recurrent cases. The great advantage of MRI is its ability to demonstrate secondary extensions, which may be missed at surgery and which are the cause of persistence (Figure 73.43). Fistulography and computed tomography (CT) both have limitations but are useful techniques if an extrasphincteric fistula is suspected.

Surgical management

Patients with minimal symptoms, especially if they have compromised sphincters, may be managed expectantly. Eradication of sepsis requires surgery, the aim of which must be balanced with the preservation of continence. Most fistulae are relatively straightforward to deal with; however, a minority are extremely problematic and are not the realm of the ‘occasional proctologist’. The multitude of strategies advocated attests to these difficult situations; comparisons between techniques are difficult to make because of the heterogeneity of patient groups, the variability in classification, the inapplicability of certain techniques in some situations, inadequate reporting of functional outcomes, inadequate follow up and surgeon preference over-riding entry into prospective randomised trials.

Fistulotomy

That the fistulous track must be laid open from its termination to its source was a rule promulgated by John of Arderne more than 600 years ago. Fistulotomy, or laying open, is the surest way of getting rid of a fistula, but, by definition, it involves division of all those structures lying between the external and internal openings. It is therefore applied mainly to intersphincteric fistulae and trans-sphincteric fistulae involving less than 30 per cent of the voluntary musculature (but not anteriorly placed fistulae in women); however, even then, it is not immune to postoperative defects in continence. After full examination under anaesthesia in the lithotomy or prone jack-knife position, during which the internal opening should have been identified, a grooved fistula probe is passed from the external to the internal opening (Figure 73.44), the amount of sphincter below and above the probe is noted and, if indicated, the track is laid open over the probe. Granulation tissue is curetted and sent for histological appraisal and the wound edges are trimmed. Secondary tracks, often identified as granulation tissue that persists despite curettage, should be laid open or drained. Marsupialisation reduces wound size and speeds up healing. Primary tracks crossing the external sphincter more deeply have been managed with good outcomes by fistulotomy and immediate reconstitution of the divided muscle – failure to eradicate all sepsis and subsequent breakdown of the repair, however, are very problematic. Alternatively, a staged fistulotomy may be carried out in which secondary tracks are laid open and only part of the sphincter enclosed by the primary track is divided, with the remainder encircled by a loose seton. After sufficient time for healing of the wound and fibrosis, the seton-enclosed track is divided at a second stage.

Fistulectomy

This technique involves coring out of the fistula, usually by diathermy cautery; it allows better definition of fistula anatomy than fistulotomy, especially the level at which the track crosses the sphincters and the presence of secondary extensions. If the sphincteric component of the fistula is deemed low enough to allow safe fistulotomy, then this may proceed (at the expense of longer healing times than conventional fistulotomy). If laying open is not advisable, then the sphincteric component can be managed by another method.

Setons

Setons (Latin: seta, bristle) have been used in a variety of ways in fistula surgery and it is important for surgeons to be clear about what they are trying to achieve in a particular situation. Loose setons are tied such that there is no tension upon the encircled tissue; there is no intent to cut the tissue. A variety of materials have been used, but the seton should be non-absorbable, non-degenerative and comfortable. Tight or cutting setons are placed with the intention of cutting through the enclosed muscle.

Figure 73.43 Coronal magnetic resonance imaging (MRI) scan (STIR sequence) demonstrating a primary track running up the right ischiorectal space (short white arrow), which then crosses the sphincters to open into the anal canal just below the puborectalis. However, there is a blind secondary extension (long white arrow) passing to the contralateral side in the roof of the left ischiorectal fossa (and involving the levators), which was missed at surgery and which was the cause of fistula persistence.
Uses of loose setons
- For long-term palliation to avoid septic and painful exacerbations by establishing effective drainage; most often in Crohn’s disease and in those with problematic fistulae not wishing to countenance the possibility of incontinence.
- Used before ‘advanced’ techniques (fistulectomy, advancement flap, cutting seton); acute sepsis and secondary extensions are eradicated and a loose seton is passed across the sphincteric component of the primary track to simplify the fistula and allow fibrosis.
- As part of a staged fistulotomy.
- As part of a therapeutic strategy to preserve the external sphincter in trans-sphincteric fistulae. Secondary tracks in the ischiorectal fossa are laid open. Access to the site where the primary track crosses the external sphincter may sometimes necessitate division of the anococcygeal ligaments to reach the deep post-anal space. The internal sphincter is laid open to the level of the internal opening (or higher if there is a cephalad intersphincteric extension) to eradicate the presumed source and the sepsis in the intersphincteric space. A seton is then passed along the residual track around the denuded external sphincter and tied loosely, and the wounds are dressed. Initial postoperative management includes daily wound irrigation and light wound redressing. The seton is left in place for three months and, if there is evidence of good healing, simply removed. Such a strategy certainly protects against the consequences of external sphincter division, with an incidence of healing in the short term of 50–60 per cent.

Uses of cutting setons
Cutting setons aim to achieve the high fistula eradication rates associated with fistulotomy, but without the degree of functional impairment endowed by division of the sphincters at a single stage. The enclosed muscle is gradually severed (‘cheese wiring through ice’) such that the divided muscles do not spring apart, and the site of the fistula track is replaced by a thin line of fibrosis as it is brought down. Some recommend prior

Figure 73.44 Fistulotomy. A grooved probe is passed from the external to internal openings (a) and the track laid open over the probe (b). The track is curetted to remove granulation tissue (c), the edges of the wound are trimmed and the wound may then be marsupialised (d). Reproduced with permission from Nicholls RJ, Dozois RR. Surgery of the colon and rectum. Edinburgh: Churchill Livingstone, 1997.
internal sphincter division, others incorporation of the internal sphincter within the cutting seton. A variety of seton material has been used, either elastic and 'self-cutting' or non-elastic and tightened at intervals, with the sphincter being divided at varying speeds. In eastern parts of the world, the same aim has been achieved by chemical cautery using an Ayurvedic method, known in India as Kshara sutra, in which a specially prepared seton thread burns through the enclosed tissue. This outpatient method has been shown to be equivalent to one-stage fistulotomy in patients with intersphincteric and distal trans-sphincteric fistulae.

Advancement flaps
When the sphincter complex is not too indurated and adequate intra-anal access can be obtained, the advancement flap technique can be employed, which aims to preserve both anatomy and function. The principles are prior elimination of acute sepsis and secondary tracks, with ideally a direct track from internal to external openings; coring out of the entire track; and closure of the communication with the anal lumen with an adequately vascularised flap consisting of mucosa and internal sphincter, sutured without tension to the anoderm, well distant from the site of the (excised) internal opening. Modifications include flap orientation (proximally or distally based) and thickness (mucosal, partial or full-thickness internal sphincter), and treatment of the external wound.

Biological agents
The functional consequences of fistulotomy and the poorer eradication rates of sphincter-preserving techniques have led to a search for agents that essentially plug and seal the track and allow ingrowth of healthy tissue to replace it (Summary box 73.14). Intuitively, success must depend on the biomaterial itself and the environment into which it is placed. The poor long-term results of fibrin glue probably result from its short-term results associ

**Summary box 73.14**

**Anorectal fistulae**
- Are common and may be simple or complex
- Are classified according to their relationship to the anal sphincters
- May be associated with underlying disease, such as tuberculosis or Crohn’s disease
- Laying open is the surest method of eradication, but sphincter division may result in incontinence

**HIDRADENITIS SUPPURATIVA**

This is a chronic suppurative condition of apocrine gland-bearing skin, which is found in the axillae, submammary regions, nape of the neck, groin, mons pubis, inner thighs and sides of the scrotum, as well as the perineum and buttocks, and is a source of considerable physical and psychological morbidity. There is no confirmatory test or specific characteristic for diagnosis, which makes definition difficult. Acne, pilonidal sinus and chronic scalp folliculitis may coexist with hidradenitis suppurativa in the condition ‘follicular occlusion tetrad’.

**Pathology**

Occlusion of gland ducts leads to bacterial proliferation, gland rupture and spread of infection and epithelial components into the surrounding soft tissue and to adjacent glands. Secondary infection (with *Staphylococcus aureus*, *Streptococcus milleri* and anaerobes) causes further local extension, skin damage and deformity, with multiple communicating subcutaneous fistulae. There is some evidence that the disease may be related to a relative androgen excess.

**Presentation**

The condition is not seen before puberty and rarely presents after the fourth decade of life. Overall, it is three times more common in women than men, although anogenital disease is more common in men, and obesity is a common association. When affecting the perineum, lesions begin as multiple raised boils, with recurrent lesions within the same vicinity leading to sinus tract formation, bridged scarring and multiple points of discharge. Rarely, it may involve the anal canal anoderm, but it does not extend above the dentate line or involve the sphincter muscles themselves.

**Differential diagnosis**

In the early stages, distinction from furunculosis can be difficult. Crohn’s disease, cryptoglandular fistula, pilonidal sinus, tuberculosis, actinomycosis, lymphogranuloma venereum and granuloma inguinale must be considered when later stages present.

**Treatment**

In the early stages, general measures, including weight reduction and antiseptic soaps, may be helpful. Antibiotics may induce remission, but often the disease relapses and progresses, at which point surgery is indicated. Inadequate treatment may lead to prolonged morbidity but any surgery should be less debilitating than the condition. Surgical intervention ranges from simple incision and drainage of acute sepsis to radical excision of all apocrine gland-bearing skin. Careful laying open of all tracks, possibly as a staged procedure according to anatomical location, is an option that appeals to many patients. Radical excision requires closure by skin graft or rotation flap and, occasionally, a defunctioning colostomy to allow healing.

**CONDYLOMATATA ACCUMINATA (ANAL WARTS)**

There is increasing evidence that sexually transmitted infection with human papillomavirus (HPV) forms the aetiological basis of anal and perianal warts, anal intraepithelial neoplasia (AIN) and squamous cell carcinoma of the anus. In those areas of the
world where sexual promiscuity (especially anal intercourse) is more common, and in immunocompromised individuals (HIV-infected individuals and transplant recipients), there have been dramatic increases in the incidence of these conditions over the last 30 years, most importantly of AIN and anal cancers. Similar virally induced changes have been noted in the genital tracts of women (vulval intraepithelial neoplasia (VIN), cervical intraepithelial neoplasia (CIN) and cancers). There are over 80 subtypes of HPV but certain subtypes (16, 18, 31, 33) are associated with a greater risk of progression to dysplasia and malignancy.

Condylomata acuminata is the most common sexually transmitted disease encountered by colorectal surgeons and is most frequently observed in homosexual men. Associated warts on the penis and along the female genital tract are common.

**Presentation**

Many are asymptomatic but pruritus, discharge, bleeding and pain are usual presenting complaints. In the early stages, examination reveals separate pinkish-white warts close to the anal margin and also often on the anoderm within the distal anal canal. Later, the warts enlarge, coalesce and carpet the skin. Rarely, relentless growth results in giant condylomata (Buschke–Löwenstein tumour), which may obliterate the anal orifice. The diagnosis is aided by aceto-whitening upon application of acetic acid but confirmed by biopsy, which will also indicate the presence or absence of dysplasia.

**Treatment**

Because of the field effect endowed by viral skin infection, long-term resolution can be problematic. Careful serial application of 25 per cent podophyllin to discrete warts on the perianal skin is often used; however, it cannot be used intra-anally. Surgical excision under local, regional or general anaesthesia involves raising and separating the lesions with local infiltration of dilute adrenaline, which allows more accurate scissor or electrocautery excision to maximise the preservation of normal skin.

**ANAL INTRAEPITHELIAL NEOPLASIA**

Anal intraepithelial neoplasia (Figure 73.45) is a multifocal virally induced dysplasia of the perianal or intra-anal epidermis which is associated with the human papilloma virus (most frequently subtypes 6, 11, 16 and 18). The prevalence is <1 per cent of the population with a rising incidence especially in those areas where anoreceptive intercourse and HIV are prevalent. At-risk groups include patients with HIV, as well as immunocompromised patients, women with a history of other genital intraepithelial neoplasia (VIN and CIN) and patients with extensive anogenital condylomata. Patients may be asymptomatic and the diagnosis is often a histological surprise, although increasing numbers in high-risk groups are picked up on anal cytology. It is classified according to the degree of dysplasia on biopsy into AIN I, AIN II and AIN III, according to the lack of keratocyte maturation and extension of the proliferative zone from the lower third (AIN I) to the full thickness of the epithelium (AIN III), in the same manner as cervical or vulval dysplasia. The natural history is uncertain, but progression from AIN II to AIN III to invasive carcinoma has been observed, notably in the immunocompromised. The term Bowen’s disease should probably be avoided.

**Presentation**

Around 10 per cent of AIN lesions are diagnosed by the pathologist after excision of abnormal skin lesions. Low-grade lesions may be raised and similar to anal condylomata; however, AIN III lesions are more often flat and may be white, grey, purple or brown in colour. Ulceration would suggest progression to invasive anal carcinoma. Patients’ symptoms include pruritis, pain, bleeding and discharge. AIN is present in 28–35 per cent of excised anal warts. Approximately 10 per cent of AIN III lesions will progress to anal carcinoma at five years. Regression of AIN III rarely occurs, but AIN I and AIN II may regress. The association between AIN III and carcinoma is strengthened by the findings of AIN III in 80 per cent of anal cancer biopsies.

**Diagnosis and management**

A high index of suspicion and targeted biopsy yields the diagnosis, whereas multiple (mapping) biopsies give an indication of the extent and overall severity of the disease. AIN II and III should be regularly monitored clinically and, if necessary, by repeat biopsy to exclude invasive disease. Specialised centres may offer colposcopy of the anus (anoscopy) utilising 5 per cent acetic acid with Lugol’s iodine to assess in vivo the dysplastic areas of the anus. The affected areas show up white and can be biopsied. Focal disease may be excised and local excision is effective for lesions <30 per cent of the circumference of the anus. More widespread disease can be dealt with surgically by wide local excision and closure of the resultant defect by flap or skin graft, with or without covering colostomy (especially if there is intra-anal disease). However, for a condition with uncertain malignant potential, this approach should be used with caution as it carries with it significant morbidity. It is important to remember that female patients are at risk of other anogenital intraepithelial neoplasia; it is recommended that those with AIN III have a yearly cervical smear test.

Topical imiquimod, 5 per cent, or oral retinoids have some effect on the progression of dysplasia and can cause regression by at least two histological grades. Other newer options may include anti-human papilloma virus treatment and vaccination may reduce the incidence long term.

Abraham Buschke, 1868–1943, a German dermatologist.

LW Löwenstein described this condition in 1939.

John Templeton Bowen, 1857–1941. Professor of Dermatology, Harvard University Medical School, Boston, MA, USA, described this intradermal precancerous skin lesion in 1912.
NON-MALIGNANT STRICTURES – ANAL STENOSIS

**Spasmodic**
An anal fissure causes spasm of the internal sphincter. Rarely, a spasmodic stricture accompanies secondary megacolon, possibly as a result of the chronic use of laxatives.

**Organic**
Anal stenosis is a rare but serious complication of anorectal surgery, 90 per cent are seen after haemorrhoidectomy. Other causes include trauma, inflammatory bowel disease, radiation treatment, sexually transmitted disease, tuberculosis and some skin conditions, e.g. scleroderma.

**Postoperative stricture**
This sometimes follows a haemorrhoidectomy performed incorrectly. Removal of excess anoderm and mucosa without adequate skin bridges can lead to scarring and structuring. Stenosis can be seen after stapled haemorrhoidopexy (0.8–5 per cent) and low coloanal anastomoses, especially if a stapling gun is used, but these are really low rectal stenoses.

**Irradiation stricture**
This is an aftermath of irradiation and is particularly seen after chemoradiation for anal carcinoma when a wide area of skin and anoderm are irradiated. It can be seen after irradiation for any pelvic tumours.

**Senile anal stenosis**
A condition of chronic internal sphincter contraction is sometimes seen in the elderly. Increasing constipation is present, with pronounced straining at stool. Faecal impaction is liable to occur. The muscle is rigid and feels like a tight rubber ring. There is no evidence of a fissure-in-ano. The treatment is dilatation at frequent intervals.

**Lymphogranuloma inguinale**
Lymphogranuloma inguinale (see Chapter 72) is by far the most frequent cause of a tubular inflammatory stricture of the rectum and 80 per cent of the sufferers are women. Frei’s reaction is usually positive. This variety of rectal stricture is particularly common in black populations and may be accompanied by elephantiasis of the labia majora. In the early stages, antibiotic treatment may lead to cure. In advanced cases, excision of the rectum is required.

**Inflammatory bowel disease**
Stricture of the anorectum may complicate Crohn’s disease and, in this instance, the stricture is annular and often more than one is present. These stenoses are characterised by transmural scarring and inflammation. Occasionally, an anal stricture may occur in ulcerative colitis. Until a biopsy is obtained, a carcinoma should be suspected if a stricture is found.

**Endometriosis**
Endometriosis of the rectovaginal septum may present as a stricture. There is usually a history of frequent menstrual periods with severe pain during the first 2 days of the menstrual flow.

**Neoplastic**
When free bleeding occurs after dilatation of a supposed inflammatory stricture, carcinoma should be suspected (Grey Turner) and a portion of the stricture should be removed for biopsy. Sometimes in these cases, repeated biopsies show inflammatory tissue only. If, however, the symptoms show a marked progression, malignancy should be strongly suspected.

**Clinical features**
Increasing difficulty in defaecation is the leading symptom. The patient finds that increasingly large doses of aperients are required and, if the stools are formed, they are ‘pipe-stem’ in shape. In cases of inflammatory stricture, tenesmus, bleeding and the passage of mucus are superadded. Sometimes the patient comes under observation only when subacute or acute intestinal obstruction has supervened.

**Rectal examination**
The finger encounters a sharply defined shelf-like interruption of the lumen. If the calibre is large enough to admit the finger, it should be noted whether the stricture is annular or tubular. Sometimes this point can be determined only after dilatation. A biopsy of the stricture must be taken. Often the examination will be painful and needs to be performed under general anaesthesia when biopsies and gentle, graduated dilatation may be undertaken.

**Treatment**
Before starting treatment, it is important to ascertain the cause of the stricture. If associated with Crohn’s disease, an anoplasty is contraindicated. Non-operative treatment is recommended for mild stenosis. The use of stool softeners and fibre supplements helps aid the passage of stools.

**Prophylactic**
The passage of an anal dilator during convalescence after haemorrhoidectomy greatly reduces the incidence of postoperative stricture. Efficient treatment of lymphogranuloma inguinale in its early stages should lessen the frequency of stricture from that cause.

**Dilatation**
Anal dilatation can be performed under general anaesthesia and then, by the patient, using an anal dilator. For anal and many rectal strictures, dilatation at regular intervals is all that is required.

**Anoplasty**
For severe anal stenosis, an anoplasty is used to replace loss of anal tissue. The stricture is incised and a rotation or advancement flap of skin and subcutaneous tissue replaces the defect
and enlarges the anal orifice (Figure 73.46). This technique is particularly useful for postoperative strictures.

**Colostomy**

Colostomy must be undertaken when a stricture is causing intestinal obstruction and in advanced cases of stricture complicated by fistulae-in-ano. In selected cases, this can be followed by restorative resection of the stricture-bearing area. If this step is anticipated, a loop ileostomy is constructed.

**Rectal excision and coloanal anastomosis**

When the strictures are at or just above the anorectal junction and are associated with a normal anal canal, but irreversible changes necessitate removal of the area, excision can be followed by a coloanal anastomosis with good functional results (Summary box 73.15).

### Summary box 73.15

**Benign anal stricture**
- May be spasmodic or organic
- May be iatrogenic, e.g. after haemorrhoidectomy or repair of imperforate anus
- Biopsy must be taken to rule out malignancy
- Can usually be managed by regular dilatation
- Severe anal stenosis may require an anoplasty

### Malignant Tumours

**Malignant lesions of the anus and anal canal**

Anal malignancy is rare and accounts for less than 2 per cent of all large bowel cancers. The crude incidence rate is 0.65 per 100,000. Those arising below the dentate line are usually squamous, whereas those above are variously termed basaloïd, cloacogenic or transitional. Collectively, they are known as epidermoid carcinomas, and management and prognosis is similar for this group, which accounts for >70 per cent of anal malignancies. Adenocarcinomas are the next most common. Other tumours include melanoma, lymphoma and sarcoma.

**Squamous cell carcinoma**

Although rare, the incidence of anal squamous cell carcinoma (SCC) is rising, with a direct association with HPV infection, AIN and immunosuppression. Anal SCC is associated with HPV (especially subtypes 16, 18, 31 or 33) in 70–90 per cent of cases (Figure 73.47). Patients at increased risk are those with HIV infection, recipients of organ transplants (renal transplant patients have a 100-fold increased risk) and those with a past history of cancers at ‘sexually accessible’ sites (usually genital). Pain and bleeding are the most common symptoms and the disease is thus often initially misdiagnosed as a benign condition, highlighting the need for a level of suspicion and adequate examination. A mass, pruritus or discharge is less common. Advanced tumours may cause faecal incontinence by invasion of the sphincters and, in women, anterior extension may result in anovaginal fistulation. On examination, anal margin tumours look like malignant ulcers. There may be associated HPV lesions. Anal canal tumours are palpable as irregular indurated tender ulceration. Sphincter involvement may be evident.

**Management**

Historically, early anal margin tumours were treated by local excision and anal canal tumours by abdominoperineal excision of the rectum. Nowadays, primary treatment is by chemoradiotherapy (combined modality therapy (CMT)) (Nigro), the chemotherapy usually including a combination of 5-fluorouracil (5-FU) with mitomycin C or cisplatin. Metastases are rare at presentation (5 per cent) and treatment is aimed at local control. Initial staging involves a clinical examination and biopsy of the primary tumour, as well as examination of inguinal nodes. Local staging is by MRI scanning and CT is used to assess lungs and abdomen for metastatic spread. Positron emission tomography (PET) CT may help in equivocal inguinal node assessment. The surgeon has an important role in management: initial diagnosis is surgical; small marginal tumours are still best treated by local excision; radical surgery is indicated in those with persistent or recurrent disease following CMT; and a defunctioning stoma may be indicated for those in whom treatment and disease regression is associated with radionecrosis, incontinence or fistula. Despite good results with chemoradiotherapy 20–25 per cent of patients will have local disease relapse. After thorough assessment, these patients may require radical abdominoperineal resection, including excision of the posterior wall of the vagina in 70 per cent of women and reconstruction of the perineum using myocutaneous flaps.

**Other anal malignancies**

Adenocarcinomata within the anal canal are usually extensions of distal rectal cancers. Rarely, adenocarcinoma may arise from anal glandular epithelium or develop within a longstanding...
(usually complex) anal fistula; treatment is as for low rectal cancers (i.e. abdominoperineal excision of the rectum (APER) with or without previous radiotherapy or chemoradiotherapy), but prognosis is less good. Melanocytes can be found in the transitional zone of the anal canal. Malignant melanoma of the anus is very rare and usually presents as a bluish-black soft mass that may mimic a thrombosed external pile, although it may be amelanotic (Figure 73.48). The prognosis, irrespective of treatment, is extremely poor. Perianal Paget’s disease is exceedingly rare (Summary box 73.16).

Summary box 73.16

Anal cancer
- Uncommon tumour, which is usually a squamous cell carcinoma
- Associated with human papilloma virus (HPV)
- More prevalent in patients with HIV infection
- May affect the anal verge or anal canal
- Lymphatic spread is to the inguinal lymph nodes
- Treatment is by chemoradiotherapy in the first instance
- Major ablative surgery is required if the above fails

CHAPTER 74

Urinary symptoms and investigations

LEARNING OBJECTIVES

To recognise and understand:
• The major symptoms of urological disease

• The most common urological investigations

URINARY SYMPTOMS

Haematuria

Blood in the urine (haematuria) may be the only indication of cancer and other pathology in the urinary tract (Figure 74.1). Microscopic haematuria may be detected by dipstick testing in a routine health check. A substantial haemorrhage imparts a red or brownish tinge to the urine (macroscopic haematuria) and the patient may pass clots. False-positive stick tests and the discoloured urine caused by beetroot and some drugs (e.g., Dindevan (phenindione), Pyridium (phenazopyridine) and Furadantin (nitrofurantoin)) are distinguishable by the absence of red blood cells on urinary microscopy.

Haematuria may be intermittent or persistent. If the patient experiences pain with haematuria, the characteristics of the pain may help to identify the source of the bleeding. If there is a malignant cause for the haematuria, there is usually no pain. In practice, all patients with haematuria should be investigated even if they are taking anticoagulant drugs. In many, all tests will be negative: the chance of finding a urological cause in patients under 40 years of age with microscopic haematuria is small. However, bleeding into the urinary tract may be caused by an occult nephropathy so it is important to check for significant proteinuria and hypertension in these patients (Summary box 74.1).

Pain

Renal pain

A deep-seated, sickening ache in the loin characterises acute upper urinary tract inflammation or obstruction, probably as the result of stretching of the capsule of the kidney. Even small and peripheral kidney stones may cause pain, even in the absence of infection. Large slow-growing masses such as tumours or cysts

Figure 74.1 The more common causes of haematuria.

Summary box 74.1

Haematuria

- Is always abnormal whether microscopic or macroscopic
- May be caused by a lesion anywhere in the urinary tract
- Is investigated by:
  - examination of midstream specimen for infection
  - cytological examination of a urine specimen
  - intravenous urogram and/or urinary tract ultrasound scan
  - flexible or rigid cystoscopy
- Is commonly caused by urinary infection, especially in young women
are commonly painless. When the cause is inflammatory, there may be local deep tenderness and occasionally reflex spasm of the psoas muscle and involuntary flexion of the hip joint.

**Ureteric colic**
This is an acute pain felt in the loin and radiating to the ipsilateral iliac fossa and genitalia. The patient often rolls around in agony as waves of excruciating pain are imposed upon a continuing background of discomfort. Contrast this with the patient suffering from peritoneal pain, who lies still because movement hurts.

Blood clot or a sloughed renal papilla may give identical pain. The site of the pain is a partial guide to the progress of a stone: the more the pain radiates into the groin, the more distal the stone. Local tenderness is much less than would be expected from the severity of the pain (Summary box 74.2).

**Bladder pain**
Bladder pain is a suprapubic discomfort worsened by bladder filling. In men, a sharp pain misleadingly referred to the tip of the penis is the result of irritation of the bladder trigone. Severe inflammation of the bladder can cause strangury, an acute wrenching discomfort at the end of micturition.

**Perineal pain**
This is experienced as a penetrating ache in the perineum and rectum, sometimes with associated inguinal discomfort. The patient is characteristically depressed by the relentless pain. Pelvic pain is often blamed on ‘chronic prostatitis’, ‘prostadynia’ or ‘chronic prostate pain syndrome’, but it occurs in both men and women. It is notoriously difficult to treat, a characteristic shared with various chronic scrotal pain syndromes.

**Urethral pain**
Urethral pain is a scalding or burning felt in the vulva or penis, especially during voiding (Summary box 74.3).

**Altered bladder function**
The normal bladder has two phases of function. During the filling phase, the bladder acts as a reservoir to collect urine until it is emptied in the voiding phase. Inappropriate contraction of the bladder detrusor muscle during filling (instability) is perceived as a sensation of urgency. There may be frequent micturition with or without urge incontinence. Sleep may be disturbed by nocturia. Instability may be idiopathic in both sexes or part of the bladder response to outflow obstruction, notably in prostatic disease. When detrusor instability has a demonstrable neurological cause, it is known as hyperreflexia.

Symptoms of impaired emptying are most commonly the result of bladder outflow obstruction, but detrusor failure presents a similar picture. The patient has difficulty initiating voiding (hesitancy) and the stream is variable or slow. Abdominal straining improves the weak flow. When micturition is complete, the bladder may still feel full. With time, the bladder becomes chronically overfilled. Urine spills out, typically at night when sleep halts trips to the lavatory (chronic retention with overflow) (Summary box 74.4).

**INVESTIGATION OF THE URINARY TRACT**

With the exception of renal and scrotal masses or tenderness, a palpable bladder or an abnormal prostate on digital rectal examination, urological conditions are most likely to be diagnosed from the history or by investigations.

**Urine**
Dipsticks (Multistix, Labstix) are a convenient way to screen urine for blood, protein or nitrites. When the urine is macroscopically clear and negative on dipstick testing, microscopy and culture of a midstream clean-catch specimen are usually negative. The presence of protein and nitrites (produced by organisms in the urine) indicates the likelihood of infection. The significance of microscopic haematuria is discussed above. Some dipsticks also give an indication of the pH and specific gravity of the urine.

Microscopy confirms the presence of white and red blood cells in the urine, and bacteria may also be visible. Protein casts suggest disease of the renal parenchyma, as does red cell dysmophia seen on phase contrast microscopy. Schistosoma ova have a typical appearance (Figure 74.2), and vegetable or meat fibres may be present if there is a fistula connecting the bowel with the urinary tract.

Cytological examination of the urinary sediment is sensitive and specific for poorly differentiated transitional cell tumours anywhere in the urinary tract. However, false negatives are common when the cancer is well differentiated. A chemical test...
Levels of blood urea and serum creatinine can be affected by various factors but, when taken together, they serve as a useful clinical guide to overall renal function. A creatinine clearance test will give an approximate value for glomerular filtration rate but is prone to error. A more accurate assessment of glomerular function can be obtained from an estimate of the clearance of chromium-51-labelled ethylenediaminetetraacetic acid. Surgeons will usually call on their nephrological colleagues for more detailed investigations of tubular function and renal blood flow.

The specific gravity of the urine is fixed at a low level when the kidney loses the power to concentrate because of renal tubular dysfunction. Estimation of the urinary loss of sodium, \( \beta \)-microglobulin or the tubular enzyme N-acetylgalucosamine (NAG) will further define the nature of any functional impairment (Summary box 74.6).

**Imaging**

A plain abdominal x-ray showing the kidneys, ureters and bladder (the KUB) is a simple and useful test. Abnormalities of the spine and other bony structures including scoliosis, spina bifida, degenerative disease of the spine, metastases, fractures and arthritis may be relevant to the urological diagnosis. The soft-tissue renal shadows, outlined by their more radiolucent fatty coverings, overlie the upper attachments of the psoas muscles. A full bladder often presents a hazy outline arising from the pelvis.

Most urinary calculi absorb x-rays and lie in the region of the renal shadows and along the course of each ureter. These normally follow the tips of the transverse processes of the vertebrae, cross the sacroiliac joints and head for the ischial spine before hooking medially towards the bladder base. Stones with a low calcium content and those overlying bony structures may be difficult to see on the plain film. Pelvic phleboliths are very common and can look like lower ureteric calculi. Uric acid stones are the most common radiolucent calculi (Summary box 74.7).

**Summary box 74.6**

**Tests of renal function**

- Elevated blood urea and serum creatinine levels usually indicate a significant impairment of renal function
- More sophisticated renal assessment is required to quantify the functional deficit

**Summary box 74.7**

**Straight abdominal radiograph**

- Most urinary calculi are radiodense
- Uric acid calculi are typically radiolucent

**Tests of renal function**

More than 70 per cent of kidney function must be lost before renal failure becomes evident: there is a large functional reserve. It follows that renal damage must be extensive before changes occur in blood constituents whose level is controlled by renal excretion. Such damage is of three main types: reduction of renal plasma flow, destruction of glomeruli and impairment of tubular function. In severe hypertension or renal artery stenosis, the plasma flow is impaired. In glomerulonephritis or acute cortical necrosis, there is a loss of glomeruli, whereas in pyelonephritis, tubular function is most severely affected. In obstructive nephropathy, back pressure on the renal parenchyma causes all three types of damage.

Investigation of the urinary tract
Intravenous urography (urography)

Excretion renography has been a mainstay of urological investigation since the introduction of intravenous contrast media in the 1930s. These are organic chemicals to which iodine atoms are attached to absorb x-rays. When such a chemical is injected intravenously, it is filtered from the blood by the glomeruli and does not undergo tubular absorption. As a result, it rapidly passes through the renal parenchyma into the urine, which it renders radio-opaque.

Although intravenous urography (IVU) gives excellent images of the urinary tract (Figure 74.3), its use should be restricted because in a few patients the iodine in the contrast medium may cause an anaphylactic reaction. Patients with a history of allergy, atopy and eczema are particularly vulnerable, but severe reactions may occur without warning. Less invasive and dangerous imaging techniques are clearly to be preferred if they are able to give comparable diagnostic information (Summary box 74.8).

**Summary box 74.8**

<table>

</tr>
</tbody>
</table>

**Preparation**

A laxative will clear faeces that might otherwise obscure details of urinary tract anatomy. Modest fluid restriction is permissible, but dehydration is dangerous because it may precipitate acute renal failure.

**Technique**

The patient is observed carefully while the first few drops of contrast medium (Urografin or Niopam 370) are injected. The earliest films show the renal parenchyma opacified by contrast medium – the nephrogram phase. A delayed nephrogram on one side indicates unilateral functional impairment. Distortion of the renal outline or failure of part of the kidney to function suggests a space-occupying lesion.

After a few minutes, the contrast is excreted into the collecting system, opacifying the calyces and the renal pelvis. Later films show the ureters and, at the end of the study, the patient is asked to pass urine and a final film is taken to show details of the bladder area. It is important to bear in mind that the static images of IVU provide only snapshots of dynamic events in the urinary tract. The appearance of a normal ureter changes as peristaltic waves of contraction pass along it.

IVU is particularly valuable to demonstrate tumours and calculi within the urinary tract, which are sometimes difficult to see on ultrasonography. It may also be useful to show details of abnormal anatomy that are difficult to interpret on an ultrasonogram.

As ultrasonography and other forms of scanning have become more sophisticated, the indications for the urogram are fewer and it may eventually fall into disuse. Obstruction to the upper urinary tract interferes with transport of contrast medium into the urine, which will show up as a non-functioning kidney on the standard urogram films. In these circumstances, a further x-ray taken many hours after injection of the contrast medium may show hazy opacification of a dilated system. Distortion of the calyces or the renal outline can equally be caused by a tumour or by harmless simple cysts. In each of these cases, more information can be obtained from ultrasonography or computed tomography (CT).

Retrograde ureteropyelography (synonym: retrograde ureterogram)

A ureteric catheter is passed into the ureteric orifice through a cystoscope (Figure 74.4). Contrast medium injected through the catheter will demonstrate the anatomy of the upper urinary tract. This is particularly useful if there is doubt about an intraluminal lesion (Figure 74.5) or if renal function is deficient (before surgery for pelvicureteric junction obstruction, for instance). When a transitional tumour is found, it can be sampled by aspiration of urine from the upper tract or by brush biopsy. Retrograde ureteropyelography is possible under topical urethral anaesthesia using a flexible cystoscope. Introducing infection into a poorly draining part of the system carries a serious risk of septicaemia. If there is to be any delay in correcting the blockage surgically, facilities must be available to decompress the kidney by retrograde stenting or percutaneous nephrostomy.
Antegrade pyelography
Percutaneous puncture of a dilated renal collecting system is reasonably simple. The most common indication is the placement of a nephrostomy tube to drain an obstructed infected kidney or to provide access for percutaneous nephrolithotomy. Antegrade pyelography – in which contrast medium is introduced through the nephrostomy – can be helpful when retrograde studies are prevented by obstruction at the extreme lower end of the ureter.

Digital subtraction arteriography
Refinements in radiological imaging have now almost eliminated the need for translumbar aortography. Satisfactory imaging of the renal vessels can be achieved by digital subtraction angiography after intravenous injection of contrast medium. More precise information can be obtained by intra-arterial injection through a fine catheter inserted into the femoral artery using the Seldinger technique. Arteriography is now rarely used to demonstrate tumour vasculature in a hypernephroma (Figure 74.6), but a flush venogram is useful when retrograde studies are prevented by obstruction at the extreme lower end of the ureter.

Cystography
Cystography is now most commonly a component of video-urodynamic assessment (see Chapter 76). Its role in assessing ureteric reflux in children has been largely superseded by radioisotope scanning and dynamic ultrasonography.

Urethrography
Ascending urethrography is valuable to demonstrate the extent of a urethral stricture (Figure 74.7) and the presence of false passages and diverticula associated with it. A urethrogram can be used to assess the extent of urethral trauma, but there is a serious danger that contrast medium may pass into the circulation. Lipiodol carries the danger of fat embolus and should never be used, and death has followed the use of barium emulsion. Umbradil viscous V is a radio-opaque water-soluble gel that contains the local anaesthetic lignocaine. It can be injected gently and safely using Knutsson's apparatus even if the urothelium is breached.

Venography
Extension of a renal carcinoma from the renal vein into the vena cava can usually be demonstrated by ultrasound or CT, but venography was used for this purpose.

Ultrasonography
Ultrasonography is perhaps the imaging technique most widely used in urology. Kidney size, the thickness of its cortex and the presence and degree of hydronephrosis can be measured with great accuracy. Intrarenal masses can be diagnosed as smooth walled and fluid filled (simple cysts) or solid and complex (possible tumours). Stones produce a bright ultrasonic reflection and cast an acoustic shadow (Figure 74.8). The volume of urine in the bladder before and after micturition can be calculated, and even tiny filling defects within it detected. Scrotal contents can be displayed in great detail. The prostate is accessible by the transrectal route. Only the lower ureter resists effective investigation by transabdominal ultrasonography because of its small calibre and its proximity to the large bones of the pelvis and spine (Summary box 74.9).
Arnold Friend

**Summary box 74.9**

**Ultrasonography**

- Ultrasound scanning provides broadly similar anatomical information to an intravenous urogram but without the risks.

**Transrectal ultrasonography**

This has become a routine component of the investigation of suspected carcinoma of the prostate. Most commonly, suspicion has arisen because the level of prostate-specific antigen is raised or there is an abnormality of the texture or outline of the prostate on digital rectal examination. The features of carcinoma or benign enlargement of the prostate, although not absolutely specific, are sufficiently well recognised to allow an experienced ultrasonographer to identify promising sites for transrectal fine-needle biopsy.

**Computed tomography**

CT is particularly useful to assess structures in the retroperitoneum (Figure 74.9). In renal carcinoma it will show:

- the size and site of the tumour and the degree of invasion of adjacent tissue;
- the presence of enlarged lymph nodes at the renal hilum;
- invasion of the renal vein and vena cava.

CT is of crucial importance in the initial staging and follow up of men with testicular cancer, in whom the presence of retroperitoneal lymph node masses features in advanced disease. It has also been used to stage bladder and prostate cancer, but its value is less clearcut in these diseases. Non-contrast CT is also used routinely in the diagnosis of urinary calculi (Figures 74.10 and 74.11).

**Magnetic resonance imaging and positron emission tomography**

These technologies give information about the function of organs as well as detailed structural images. As they become more widely available, they are replacing many of the routine imaging techniques.

**Radioisotope scanning**

Radioisotope scanning is used to obtain information about function in individual renal units. Diethyltriaminepentaacetic acid (DTPA) behaves in the kidney like inulin: it is filtered by the glomeruli and not absorbed by the tubules. Using a gamma camera, DTPA labelled with technetium-99m can be followed during its transit through individual kidneys to give a dynamic representation of renal function. A 99mTc-DTPA scan is particularly useful to prove that collecting system dilatation is caused by obstruction. In obstruction, radioactivity will remain in the kidney even if urine flow is stimulated by administr-
tion of a diuretic like frusemide (furosemide). Other substances (dimercaptosuccinic acid (DMSA), mercaptoacetylglycine (MAG-3) and sodium orthoiodohippurate (Hippuran)) labelled with suitable radioactive isotopes have similarly been used to investigate renal function (Figure 74.12).

Isotope bone scanning is fundamental to the staging of kidney and prostate cancers, which typically metastasise to the skeleton.

**Endoscopy**

Visual inspection of the lower urinary tract has been possible since 1877, when Nitze invented his cystoscope. A leap forward in urological endoscopy came with the introduction by Hopkins of the rod lens telescope and fibreoptic illumination. This allowed development of a family of endoscopes, which allow the urologist to visualise the upper and lower urinary tracts for diagnosis and therapy. Finally, in the early 1980s, the small calibre flexible fibrescopic cystoscope was introduced. This allows simple diagnostic cystourethroscopy, bladder biopsy and retrorgrade ureterography to be performed under topical urethral anaesthesia with minimal discomfort to the patient (Summary box 74.10).

**Summary box 74.10**

**Diagnostic examination**

- Diagnostic examination of the bladder is performed painlessly under local anaesthesia using a flexible cystoscope

**ANURIA**

Anuria is defined as the complete absence of urine production. Oliguria is present when less than 300 mL of urine is excreted in a day (Summary box 74.11).

The maintenance of renal function and urine production depends upon perfusion of the kidneys with oxygenated blood. Reduced renal blood flow or hypoxia impairs renal function. When both are present, the danger of acute renal failure is even greater.

Renal failure is traditionally divided into:

- prerenal;
- renal;
- postrenal (obstructive).

**Prerenal**

Prerenal causes of acute renal failure include:

- hypovolaemia;
- blood loss;
- sepsis;
- cardiogenic shock;
- anaesthesia;
- hypoxia.

**Hypovolaemia**

This may result from inadequate fluid intake or from excessive loss of body water. Dehydration, prolonged vomiting, diarrhoea and other abnormal gastrointestinal fluid losses, burns and excessive sweating are all common causes of hypovolaemia.

**Blood loss**

This is usually caused by trauma or surgery, but acute blood loss from the gastrointestinal tract or haemorrhage associated with childbirth may be sufficient to cause hypovolaemic renal impairment.

**Sepsis**

Gram-negative septicaemia from a urinary tract source is a particularly potent cause of bacteraemic shock. Sepsis from the biliary tract and overwhelming infection from other sites, especially in the immunocompromised individual, are also associated with acute renal failure.

**Cardiogenic shock**

Acute dysrhythmia secondary to myocardial infarction, cardiac tamponade and pulmonary embolus may all result in reduced cardiac output of often poorly oxygenated blood.

**Anaesthesia**

Hypotension is a hazard of epidural and spinal anaesthesia.

**Hypoxia**

Prolonged hypoxia from any cause may occasionally be responsible.

---

**Summary box 74.11**

**Diagnosing anuria**

- Check that the bladder is empty before diagnosing anuria
- Ultrasound the bladder

---

Max Nitze, 1848–1906, urological surgeon, Vienna, Austria.
Harold Horace Hopkins, 1918–1994, Professor of Applied Optics, The University of Reading, Reading, UK.
Renal causes of acute renal failure include:
- drugs;
- poisons;
- contrast media;
- eclampsia;
- myoglobinuria;
- incompatible blood transfusion;
- disseminated intravascular coagulation.

Drugs
Aminoglycosides, cephalosporins and diuretics can be nephrotoxic, particularly if used in combination. They are quite commonly used in patients whose renal function is already compromised by sepsis or circulatory abnormalities. Prolonged use of non-steroidal anti-inflammatory drugs (NSAIDs) can cause a chronic interstitial nephritis and papillary necrosis; they also reduce renal plasma flow and therefore have nephrotoxic properties. Angiotensin-converting enzyme inhibitors used for the control of hypertension can cause a rapid reduction in the
glomerular filtration rate; this is particularly liable to occur in patients who have a reduced renal blood flow.

Poisons
Some of these are nephrotoxic.

Contrast media
Even modern contrast media may cause renal failure when injected into a dehydrated patient with compromised renal function.

Eclampsia
The early recognition of pre-eclampsia is vital to avoid the nephrotoxic consequences of toxaemia and uncontrolled hypertension.

Myoglobinuria
The presence of myoglobin in the urine is associated with the ‘crush’ syndrome after major trauma. Less severe injuries can also cause the syndrome, especially if a compartment syndrome is unrecognised or pressure areas break down.

Incompatible blood transfusion
This may lead to renal failure with myoglobinuria.

Disseminated intravascular coagulation
Disseminated intravascular coagulation usually follows major sepsis or massive blood transfusion and may occur post-partum.

Obstructive
Obstructive causes of acute renal failure include:

- calculi;
- pelvic malignancy;
- surgery;
- retroperitoneal fibrosis;
- bilharzia;
- crystalluria.

Calculi
Renal calculus disease is probably the most common cause of acute obstruction leading to anuria. The patient is likely to have unilateral renal colic against a background of non-function of the contralateral kidney, often due to previous surgery or pre-existing obstruction by calculus.

Pelvic malignancy
Carcinomas arising from the bladder, prostate, cervix, ovary or rectum can all lead to obstruction of one or both ureters. A history of haematuria and vaginal or rectal bleeding signpost the diagnosis. A large pelvic mass is commonly palpable on bimanual examination.

Surgery
The ureters are vulnerable to damage during pelvic and retroperitoneal surgery, but injury should be avoided if proper care is taken. It is unusual, but not impossible, to damage both ureters.

Retroperitoneal fibrosis
For details of retroperitoneal fibrosis, see Chapter 75.

Bilharzia
Schistosomiasis may lead to ureteric fibrosis and stenosis, and may be responsible for the development of squamous cell carcinoma of the bladder.

Crystalluria
Uric acid crystalluria can develop in patients receiving chemotherapy for leukaemia or lymphoma unless they are given prophylactic treatment with allopurinol.

Clinical aspects
Answers to the following questions should indicate the probable cause of reduced urine output.

- Is urine being produced? Bladder catheterisation is essential if a voided sample cannot be obtained. If urine is available, check the specific gravity, look for the presence of casts (implying a renal cause), test for myoglobinuria and send a sample for culture and microscopy.

- Is there an obvious prerenal cause? This can usually be answered by clinical examination, assessment of the patient’s vital signs, examination of the fluid balance chart and measurement of the arterial oxygen concentration.

- Is there ureteric obstruction? Hydronephrosis may not be marked in acute obstruction, but ultrasonography will usually show some degree of ureteric dilatation. A plain abdominal x-ray should be checked for calculi.

- What drugs have been given recently? If a drug is thought to be responsible for renal impairment, it should obviously be withdrawn unless its use is vital.

- Is this a progression to chronic renal failure? The presence of shrunken kidneys on ultrasound, normochromic anaemia and hypertension suggest progression to a chronic state even if a previous history of renal failure is not available.

Management and treatment
Renal failure caused by acute tubular necrosis may progress through three recognisable phases:

1. oliguria;
2. the diuretic phase;
3. recovery.

The initial management is aimed at prompt restoration of the circulating volume deficit and correction of tissue hypoxia. Most patients will require a level of care that is available only in a specialised unit. As a minimum, monitoring with a pulse
oximeter and central venous pressure measurements will supplement basic observations. For patients with hypovolaemia or sepsis, inotropic support with dopamine may improve cardiac efficiency and increase renal blood flow. If urine production is not promptly restored, frusemide (furosemide) can be given, but this is not always successful and the drug itself may be nephrotoxic. Mannitol may be used as a plasma expander and osmotic diuretic, but care must be taken not to overload the circulation. The aim is to achieve the best possible blood pressure, with a central venous pressure of 7–9 cmH₂O. It may be that 100% oxygen is needed to maintain the oxygen tension (PO₂).

If these measures fail, acute tubular necrosis has supervened. Excess fluid loads must be avoided and fluid input restricted to match the reduced output plus insensible losses (500–800 mL per 24 hours depending on ambient conditions). Abnormal losses due to vomiting, nasogastric aspiration, diarrhoea or fistulae should be monitored and replaced.

A hyperkalaemic acidosis is the characteristic metabolic abnormality of the oliguric phase of renal failure. Correction of the metabolic acidosis with intravenous bicarbonate is tempting but not always advisable. Rising serum potassium is life-threatening and requires effective intervention. A calcium resuscitation enema is the simplest remedy. The ion-exchange resin can also be administered orally but is unpalatable. Cautious use of intravenous dextrose and insulin should be considered if ion exchange fails. The help of a renal physician is highly desirable because urgent dialysis may become necessary to save life (Summary box 74.12).

### Summary box 74.12

**Shared management with nephrologist**

- Enlist the help of a nephrologist at an early stage in the management of renal failure

The diuretic phase traditionally occurs between the eighth and tenth day but may be delayed as long as 6 weeks. Glomerular filtration recommences but tubular function takes longer to recover. A heavy loss of sodium and potassium can be expected, and fluid and electrolyte requirements must be carefully judged. In most patients the diuretic phase is followed by the recovery phase, but some never recover and will need renal replacement therapy if they are to survive.

Factors that influence the outcome of acute renal failure include the need for artificial ventilation, the need for inotropic support and the presence of jaundice. There is a significant mortality rate.

### Nutritional support

Many patients are unable to eat. If enteral feeding is impossible, parenteral nutrition must be administered, with extreme care to avoid circulatory overload.

### Infection

These patients are at increased risk of generalised infection. Swabs taken from the nose and throat, sputum specimens and urine, if available, should be sent for culture. If antibiotics are required, they should be non-nephrotoxic.

### General nursing care

Meticulous recording of fluid balance is obviously central to the successful management of these patients. Patients who are seriously ill or comatose need regular turning and care of pressure areas if they are to avoid pressure sores. Physiotherapy to the chest and extremities will aid recovery.

### Renal support

Renal replacement is needed for those patients in whom the oliguric or anuric phase is associated with significant uraemic symptoms (vomiting, muscular twitching, itching and altered states of consciousness) or uncontrollable hyperkalaemia (Summary box 74.13).

### Summary box 74.13

**Life-threatening hyperkalaemia**

- In acute renal failure, significant hyperkalaemia is life-threatening and should be corrected at an early stage

---

### Peritoneal dialysis

Provided that the patient has not had recent abdominal surgery, peritoneal dialysis can be performed by insertion of a fenestrated catheter under local anaesthetic. This is placed just inferior to the umbilicus in the midline. Sterile dialysis fluid is then run into the peritoneal cavity, where it equilibrates with the extracellular fluid using the peritoneum as a dialysis membrane. After a variable time, the fluid is drained into a closed drainage system. The process is repeated in cycles. Occasionally, when anuria is prolonged, a cuffed catheter needs to be inserted, as used in chronic ambulatory peritoneal dialysis. The disadvantages of acute peritoneal dialysis are the potential for introducing infection into the peritoneum and the rather slow rate of correcting metabolic imbalance, particularly hyperkalaemia.

### Haemodialysis

A few sessions of haemodialysis may be life-saving. A double lumen catheter is placed over a guidewire into one of the great veins (jugular, subclavian or femoral). Between sessions of dialysis the lines are kept patent by filling them with heparin solution. Haemodialysis can result in a rapid correction of metabolic abnormalities, but also tends to result in considerable fluctuations of the overall fluid balance. The other disadvantage is that heparinisation is necessary, and this may be undesirable after a recent surgical procedure.

### Haemofiltration

This, like haemodialysis, requires the use of an extracorporeal machine but causes much less haemodynamic upset. This may be of critical importance for the acutely ill patient.

### Obstructive renal failure

When the patient is too ill for surgery to remove the cause of obstruction to the upper urinary tract, the treatment of obstructive renal impairment is drainage, either externally using a nephrostomy or internally using an indwelling stent (Summary box 74.14).
Summary box 74.14

**Catheterisation and stents**
- Urethral or suprapubic catheterisation will relieve obstruction distal to the bladder
- Indwelling stents to relieve ureteric obstruction can be inserted cystoscopically or percutaneously

**Percutaneous nephrostomy**
Under ultrasonographic guidance and local anaesthetic, a fine bore hollow needle is introduced via the flank through the parenchyma and into the expanded collecting system of the obstructed kidney. Once it penetrates the system, contrast medium can be injected through the needle to define its exact position. A wire passed through the lumen of the needle is used to guide the insertion of a series of dilators, which enlarge the track until it will accept a suitably sized nephrostomy tube (Figure 74.13). This will drain urine and pus, provided that the latter is not too viscous. The tube is anchored firmly in place to allow continued drainage as renal function recovers.

**Insertion of a J-stent**
The ureter can be drained into the bladder by the insertion of a pigtail- or J-stent (see Figure 74.13). The procedure begins with a retrograde ureterogram under fluoroscopic control to provide an image of the ureter. This will often give an indication of the cause of the obstruction. A guidewire is introduced through the ureteric orifice and guided up the ureter into the renal pelvis. The stent is rail-roaded over the guidewire until its distal end also lies within the renal pelvis above the obstruction. When the guidewire is removed, the ends of the stent curl to form a J-shape or a pigtail to secure the device against migration. Stents can be placed under topical urethral anaesthesia using the flexible cystoscope and may be safely left in position for several months. As a foreign body in the urinary tract, stents are prone to infection and encrustation if neglected. It is vital to keep careful records to account for all stents inserted.

If the J-stent cannot be inserted cystoscopically, it may be placed from above through a nephrostomy.

**Open surgery**
This is a rarity when the minimally invasive methods described above are available. Retrograde insertion of a nephrostomy through an incision in the renal pelvis is the preferred method because it can be surprisingly difficult to locate even dilated calyces by blind puncture of the renal parenchyma.

**Further Reading**
LEARNING OBJECTIVES

To recognise and understand:
- Important congenital abnormalities of the upper urinary tract
- Important cystic diseases of the kidney
- The management of open and closed trauma to the kidney and ureter
- The aetiology, presentation and surgical management of obstruction to the upper urinary tract
- The pathophysiology of renal stone formation
- The management of urinary tract calculi
- The management of sepsis in the upper urinary tract
- Important renal neoplasms and their presentation
- The surgery of upper urinary tract tumours

SURGICAL ANATOMY

The parenchyma of each kidney usually drains into seven calyces, three upper, two middle and two lower calyces (Figure 75.1). Each of the three segments represents an anatomically distinct unit with its own blood supply. One or more renal arteries are present as physiological end arteries that provide the sole blood supply to the tissue they serve. The renal veins are commonly multiple, variable and richly anastomotic. When approached anteriorly, the main artery is typically hidden behind the renal vein.

CONGENITAL ABNORMALITIES OF THE KIDNEY

Absence of one kidney
About one in 1400 people have a single kidney (Table 75.1). Sometimes a ureter and renal pelvis are present with no kidney. The contralateral kidney is typically hypertrophied. The possible absence of the contralateral kidney must be considered when planning nephrectomy.

Renal ectopia
Ectopic kidneys are found in one in 1000 people, usually on the left near the pelvic brim. The other kidney is generally normal. A diseased ectopic kidney may present diagnostic problems and may be mistakenly excised as an unexplained pelvic mass.

Horseshoe kidney
A horseshoe kidney is a pair of ectopic kidneys fused usually at their lower poles and lying in front of the fourth lumbar vertebra and great vessels. It is found in one in 1000 necropsies and is more common in men. Upper pole fusion is rare.

Clinical features
Horseshoe kidneys are vulnerable to disease, possibly because the ureters are angulated (Figure 75.2) causing urinary stasis, infection and nephrolithiasis. A pelviureteric junction obstruction (see below) has the same consequences. Horseshoe kidney is usually a radiological diagnosis. Usually the urogram shows the lower pole calyces bilaterally point towards the midline. Rarely, all or most of the calyces are reversed (Figure 75.3). Horseshoe kidney is not a contraindication to pregnancy but may predispose to urinary complications.

Kaspar Friedrich Wolff. 1733–1794, Professor of Anatomy and Physiology, St Petersburg, Russia, described the mesonephric duct and body in 1759.
Division of the relatively avascular isthmus between the kidneys is usually only indicated in the course of surgery for abdominal aortic aneurysm. The blood supply of the horseshoe comes unpredictably from nearby major vessels (Summary box 75.1).

### Summary box 75.1

**Horseshoe kidneys**
- Horseshoe kidneys are liable to pelviureteric obstruction, infection and stone
- An unrecognised pelvic kidney may cause diagnostic confusion during surgery

**Unilateral fusion**

Unilateral fusion (synonyms: crossed dystopia, cross fused renal ectopia) is rare but the urogram is striking. Both kidneys are in one loin and usually fused. The ureter of the lower kidney crosses the midline to enter the bladder on the contralateral side. Both renal pelves can lie one above each other medial to the renal parenchyma (unilateral long kidney) or the pelvis of the crossed kidney faces laterally (unilateral S-shaped kidney; Figure 75.4).

### Congenital cystic kidneys

Congenital cystic kidneys (synonym: polycystic kidneys) are hereditary, potentially lethal and transmitted by either parent as an autosomal dominant trait. Thus, the risk of inheriting the condition is high. The disease does not usually manifest clinically before the age of 30 years.

**Pathology**

The kidneys are huge: the cysts distort the renal capsule. Cysts of various sizes contain clear fluid, thick brown material or coagulated blood. There may be a congenital cystic disease of the liver. The aetiology is uncertain.

**Clinical features in the adult**

The condition is slightly more common in women than men. There are six clinical features:

1. an irregular upper quadrant abdominal mass;
2. loin pain;
3. haematuria;
4. infection;
5. hypertension;
6. uraemia.

**Renal enlargement**

Less florid examples are revealed unexpectedly at laparotomy or on abdominal imaging. Unilateral renal swelling, in which one kidney contains larger cysts than the other, may be confused with a cystic renal tumour.

**Pain**

Pain is commonly a dull loin ache. Haemorrhage into a cyst causes more severe pain, as does a calculus passing from the diseased kidney.

**Haematuria**

Cyst rupture into the renal pelvis may cause recurrent haematuria. Profuse haematuria is uncommon.

**Infection**

Pyelonephritis is common in patients with congenital cystic kidney, presumably because of urinary stasis.

---

**Figure 75.2** Horseshoe kidney. Note the ureters passing in front of the fused lower poles.

**Figure 75.3** Urogram of a horseshoe kidney. Only rarely are all the calyces directed towards the spinal column.
Hypertension
After the age of 20 years, most patients are hypertensive.

Uraemia
Congenital cystic kidneys produce large volumes of poor quality urine with a trace of albumin but no casts or cells. Non-specific symptoms of chronic renal failure develop as functioning renal tissue is replaced by cysts. Severe anaemia is common. Signs of renal failure often begin in middle life and the patient soon needs renal replacement therapy.

Imaging
There are multiple cysts in both kidneys and sometimes cysts in the liver and other organs. Blood and debris in the cysts may mimic the heterogeneity of a cystic adenocarcinoma. Simple cysts are usually solitary and have smooth thin walls and homogeneous contents (Figure 75.5). Cytologic examination of cyst fluid obtained by fine-needle aspiration will rule out cancer.

The urogram is typical: the renal shadows are enlarged in all directions; the renal pelvis is compressed and elongated; and the calyces are stretched over the cysts (Figure 75.6).

Treatment
As kidney failure develops, a low-protein diet postpones the inevitability of renal replacement therapy. Infection, anaemia, hypertension and disturbances of calcium metabolism also need treatment by a nephrologist.

Surgery to uncap the cysts (Rovsing’s operation) is rarely indicated (Summary box 75.2).

Summary box 75.2
Polycystic kidney disease
- Inherited as an autosomal dominant trait
- An important cause of end-stage renal failure
- Pain, haematuria, infection and hypertension are common
- Often fatal in early middle age

Infantile polycystic disease
Infantile polycystic disease is a rare autosomal recessive condition. The kidneys are large and may obstruct birth. Many patients are stillborn or die from renal failure early in life.

Summary box 75.3
Simple renal cysts
- Common
- Often multiple
- Diagnosed on ultrasound
- Rarely require treatment
- Treat only if causing obstruction

Differential diagnosis
In sheep-rearing districts, hydatid cysts of the kidney are common. On the right side, they can be mistaken for a hydatid cyst of the liver. Occasionally, the patient complains of passing ‘grape skins’ (ruptured daughter cysts) in the urine. Removal of the cyst must follow the principles used in excision of hydatid cyst of the liver. For a large cyst, nephrectomy may be safer.
Aberrant renal vessels
Multiple renal arteries are most common on the left. The renal arteries are functional end-arteries, so division of an aberrant renal artery leads to infarction of a section of parenchyma. Aberrant renal veins are common and can be divided with impunity. Aberrant arteries probably do not cause hydronephrosis, although a hydronephrotic renal pelvis may bulge between renal vessels, making them noticeable (Figure 75.7).

Congenital abnormalities of the renal pelvis and ureter

Duplication of a renal pelvis
Duplication of a renal pelvis, usually unilateral and left-sided (Figure 75.8), is found in about 4 per cent of patients. The small upper renal pelvis drains the upper calyces; the larger lower renal pelvis drains the middle and lower groups of calyces.

Duplication of a ureter
Duplicated ureter is found in about 3 per cent of urograms often joining in the lower third of their course (Figure 75.9) with a common ureteric orifice. When the ureters open independently into the bladder, the ureter from the upper pelvis opens distally and medially (Figure 75.10).

Clinical features
Infection, calculus formation and pelviureteric junction obstruction are more common than in normal kidneys but most are discovered by chance. One moiety may be dysplastic and non-functioning. Two ureters opening separately may both be abnormal in function, position or both. In children, this may result in a refluxing lower pole ureter and an upper pole ureter terminating in a ureterocele with a risk of infection and/or obstruction.

An ectopic second ureteric opening is a rare cause of puzzling symptoms. In females, an ectopic ureter opens either into the urethra below the sphincter (Figure 75.11) or into the vagina. The history suggests the diagnosis which is confirmed by urography. A girl or woman who voids normally but who has dribbled urine for as long as she can remember probably has an ectopic ureteric orifice. The orifice is difficult to see because it is guarded by a valve.

In the male, the aberrant opening is above the external urethral sphincter so the patient is continent. The ureteric orifice at the apex of the trigone, the posterior urethra, in a seminal vesicle or in an ejaculatory duct is likely to be functionally abnormal, and infection is common.

Treatment
Asymptomatic duplication of the kidney is harmless. A severely diseased or atrophic moiety is effectively treated by partial nephrectomy. A refluxing ureter may need reimplanting. An ectopic ureter in the female frequently drains hydronephrotic and chronically infected renal tissue, which is best excised. Rarely, the incontinence can be cured and renal function preserved by implanting the ectopic ureter into the bladder or contralateral ureter (Summary box 75.4).
Summary box 75.4

**Duplication of the kidneys and ureters**
- Is commonly asymptomatic and harmless
- One or both moieties may be dysplastic
- There may be urinary reflux, incontinence or obstruction

### Congenital megaureter

Congenital megaureter is a rare oddity that may be bilateral and associated with other congenital anomalies. Functional obstruction at the lower end of the ureter ends in progressive dilatation and infection. The ureteric orifice appears normal and a ureteric catheter passes easily. Reflux is not a feature of the untreated condition but occurs if the ureteric orifice is opened endoscopically. Spontaneous improvement occurs but infection or deteriorating function will require refashioning and reimplantation of the affected ureter.

### Post-caval ureter

The right ureter passes behind the vena cava instead of lying to the right. If this causes obstructive symptoms, the ureter can be divided and rejoined in front of the cava. Unusually, the retrocaval portion of the ureter is fibrotic and must be excised.

### Ureterocele

Ureterocele is a cystic enlargement of the intramural ureter, probably due to congenital atresia of the ureteric orifice. Present from childhood, the condition is often unrecognised until adult life. The ‘adder head’ on excretory urography (Figure 75.12) is typical. Ureterocele is confirmed by the cystoscopic appearance of a translucent cyst enlarging and collapsing as urine flows in to it (Figure 75.13). Treatment should be avoided unless there are symptoms arising from infection and/or stone formation. Ureterocele is most common in women; occasionally, the cyst may cause obstruction to the bladder outflow by prolapsing into the internal urethral opening.

Endoscopic diathermy incision is effective treatment for a symptomatic ureterocele, although a micturating cystogram is advisable to detect postoperative urinary reflux. In advanced unilateral cases with hydronephrosis or pyonephrosis, consider nephrectomy.

### INJURIES TO THE KIDNEY

In civilian life, injuries to the kidney result most often from either blows or falls on the loin or crushing injury to the abdomen, typically in a road traffic accident. Haematuria after trivial injury to the kidney should suggest the possibility of a pre-existing disease, e.g. calculus, hydronephrosis or tuberculosis.

The range of injury extends from a small sub-capsular haematoma to a complete tear through the kidney (Figure 75.14).

---

**Adder head.** An adder is a venomous snake of the family Viperidae which is found in the UK and other parts of the world. It has a triangular shaped head.
The kidney may be partially or wholly torn from its vascular pedicle; one pole may be completely detached.

Closed renal injury is usually extraperitoneal. In young children with little extraperitoneal fat, the peritoneum, which is closely applied to the kidney, can tear with the renal capsule, leaking blood and urine into the peritoneum (Summary box 75.5).

**Summary box 75.5**

**Haemorrhage**

- Lethal haemorrhage is a serious risk in kidney trauma

---

**Clinical features of closed renal trauma**

There is local pain and tenderness, sometimes with superficial soft-tissue bruising.

**Haematuria**

Haematuria may not appear until days after the injury. Profuse bleeding may cause clot colic.

**Severe delayed haematuria**

Sudden haematuria between the third day and third week after trauma in a recovering patient is caused by a clot becoming dislodged.

**Meteorism**

Abdominal distension 24–48 hours after renal injury is probably a result of retroperitoneal haematoma implicating splanchnic nerves (Summary box 75.6).

**Summary box 75.6**

**Clinical features of closed renal trauma**

- There may be no external bruising
- Haematuria indicates kidney damage and should prompt careful monitoring and urgent investigation
- Delayed haemorrhage may occur

---

**Management and treatment**

Watchful treatment of closed renal trauma is often successful. Consider the possibility of injury to other organs at an early stage.
• Cross-match blood and secure intravenous access if there is any evidence of hypovolaemic shock or continuing haemorrhage.
• Advise bed-rest while there is macroscopic haematuria and restrict activity for a week after the urine clears.
• Administer appropriate analgesia.
• Keep hourly observations.
• Antibiotics should be given to prevent infection of the haematoma.
• Check the urine passed for haematuria and chart the result.
• Urgent intravenous urography (IVU) or contrast-enhanced CT will clarify the extent of renal damage and show that the other kidney is normal.
• Blood should be sent for grouping and serum saved for cross-matching in all cases.

Surgical exploration

Surgical exploration is necessary in less than 10 per cent of closed injuries; it is indicated if there is progressive blood loss or there is an expanding loin mass. The aim is to stop bleeding while conserving as much renal tissue as possible. A renal arteriogram performed preoperatively will help to frame an operative strategy. Embolisation may arrest the haemorrhage if a bleeding vessel can be identified.

Damage to other abdominal organs is checked during a transperitoneal approach. Release of the tamponading effect of the perirenal haematoma can result in massive haemorrhage and the surgeon must be prepared for this. When the kidney is irretrievably ruptured or avulsed from its pedicle, nephrectomy is the only course. Small tears can be sutured over a haemostatic sponge or a piece of detached muscle. Large single rents in the kidney are best dealt with by passing a tube nephrostomy through the defect and suturing the renal tissue around it. Partial nephrectomy may be practicable for localised injury.

When a solitary kidney is sufficiently damaged to need exploration, it must be repaired. Failing this, the wound is packed firmly with gauze to stop the bleeding in the hope that some renal function may be retained when the ruptured kidney heals (Summary box 75.7).

Complications

Heavy haematuria may lead to clot retention requiring bladder washout.

Pararenal pseudohydronephrosis may occur weeks later from a combination of complete cortical tear and ureteric obstruction caused by scarring.

Hypertension, resistant to drugs, resulting from renal fibrosis, may occur long after injury. Nephrectomy may be necessary.

Post-traumatic aneurysm of the renal artery (Figure 75.15) is rare. There is loin pain and a non-tender swelling may be felt if the aneurysm is large. Congestion of the parenchyma leads to intermittent haematuria. Aortography is diagnostic. Excision or nephrectomy is indicated to prevent fatal rupture of the aneurysm.

INJURIES TO THE URETER

Rupture of the ureter

This is an uncommon result of a hyperextension injury of the spine. The diagnosis is rarely made until there is swelling in the loin or iliac fossa associated with a reduced urine output. An IVU or contrast-enhanced CT shows extravasation of contrast.

Injury to one or both ureters during pelvic surgery

This occurs most often during vaginal or abdominal hysterectomy when the ureter is mistakenly divided, ligated, crushed or excised. Pre-emptive ureteric catheterisation makes it easier to identify the ureters.

Injury recognised at the time of operation

Ureterovesical continuity should be restored by one of the methods described below unless the patient’s condition is poor. Deliberate ligation of the proximal ureter and temporary percutaneous nephrostomy is then the best course until the patient is well enough for a repair (Summary box 75.8).

Summary box 75.8

Ureteric injury during operation

- Surgical trauma during pelvic surgery is the most common cause of ureteric trauma
- Preoperative catheterisation of the ureters makes them easier to protect
- Injuries discovered during surgery should be repaired immediately

Figure 75.15 Aneurysm of the renal artery containing lamellated thrombus.
Injury not recognised at the time of operation

Unilateral injuries

There are three possibilities:

1. No symptoms. Ligation of a ureter may lead to silent atrophy of the kidney. The injury may be unsuspected until the patient undergoes urological imaging.

2. Loin pain and fever, possibly with pyonephrosis, occur with infection of the obstructed system. Loss of function will be permanent unless obstruction is relieved by promptly inserting a percutaneous nephrostomy.

3. A urinary fistula develops through the abdominal or vaginal wound. The IVU or contrast-enhanced CT shows extravasation with or without obstruction of one or both ureters. Nephrostomies may be inserted and repair postponed until oedema and inflammation have subsided, but delayed repair often leaves the patient incontinent. Early repair is safe if the patient is fit for surgery.

Bilateral injury

Ligation of both ureters leads to anuria. Ureteric catheters will not pass and urgent nephrostomy or immediate surgery is essential.

Repair of the injured ureter

An open repair may be avoidable if a stent will pass the obstruction (Table 75.2). If the cut ends of the ureter can be apposed without tension, they should be joined by a spatulated anastomosis over a double pigtail catheter.

If the division is low, the bladder may be hitched and the ureter can be reimplanted. Extra length may be obtained by mobilising the kidney.

In the Boari operation (Figure 75.16), a flap of bladder wall is fashioned into a tube to replace the lower ureter. The disadvantage of implanting the ureter end to side into the contralateral ureter (a transureteroureterostomy) is that it risks converting a unilateral injury into a bilateral one.

Table 75.2 Methods for repairing a damaged ureter.

<table>

<td>Nephrectomy</td>
</tr>
</tbody>
</table>

Nephrectomy may be best when the patient’s outlook is poor and the other kidney is normal. When conservation of all renal tissue is vital, replacement of the damaged ureter by a segment of ileum is necessary (Summary box 75.9).

Summary box 75.9

Repair of ureteric injury

When surgical damage to a ureter is discovered postoperatively:

- Repair need not be delayed
- Ideally surgical repair should be performed by a urologist

HYDRONEPHROSIS

Hydronephrosis is an aseptic dilatation of the kidney caused by obstruction.

Unilateral hydronephrosis

See Summary box 75.10.

Summary box 75.10

Causes of unilateral ureteric obstruction

Extramural obstruction

- Tumour from adjacent structures, e.g. cervix, prostate, rectum, colon or caecum
- Idiopathic retroperitoneal fibrosis
- Retrocaecal ureter

Intramural obstruction

- Congenital stenosis, physiological narrowing of the pelviureteric junction leading to pelviureteric junction obstruction
- Ureterocele and congenital small ureteric orifice
- Inflammatory stricture following removal of ureteric calculus, repair of a damaged ureter or tuberculous infection
- Neoplasia of the ureter or bladder cancer involving the ureteric orifice

Intraluminal obstruction

- Calculus in the pelvis or ureter
- Sloughed papilla in papillary necrosis (especially in diabetics, analgesic abusers and sickle cell disease)
Bilateral hydronephrosis

Bilateral hydronephrosis is usually the result of urethral obstruction, but the lesions described above may occur bilaterally. When due to lower urinary obstruction, the cause may be:

- congenital:
  - posterior urethral valves;
  - urethral atresia;
- acquired:
  - benign prostatic enlargement or carcinoma of the prostate;
  - postoperative bladder neck scarring;
  - urethral stricture;
  - phimosis.

The ureters can be obstructed in their intramural course by detrusor hypertrophy caused by urethral obstruction.

Pathology

There is calyceal dilatation and pressure atrophy of the kidney. A kidney destroyed by longstanding hydronephrosis is a thin-walled, lobulated, fluid-filled sac.

Clinical features

Unilateral hydronephrosis

Unilateral hydronephrosis (commonly caused by idiopathic pelviureteric junction obstruction or calculus) is more common in women and on the right.

Presenting features include the following:

- Mild pain or dull aching in the loin, often a dragging heaviness worsened by excessive fluid intake. The kidney may be palpable.
- Intermittent hydronephrosis (Dietl’s crisis). Loin swelling is associated with acute renal pain. The pain goes and the swelling disappears when a large volume of urine is passed.
- Antenatal detection in the fetus by ultrasound scan. Many of these cases are benign, but postnatal investigation is required to detect those with significant pelviureteric junction obstruction (Summary box 75.11).

Summary box 75.11

Idiopathic pelviureteric obstruction

- May be asymptomatic
- Can present as intermittent loin pain often exacerbated by a fluid load

Bilateral hydronephrosis

From lower urinary obstruction

Symptoms of bladder outflow obstruction predominate. The kidneys are usually impalpable because renal failure intervenes before they enlarge.

From bilateral upper urinary tract obstruction

Idiopathic retroperitoneal fibrosis affects both ureters and idiopathic pelviureteric junction obstruction can be bilateral. Symptoms may be referred to one side.

From pregnancy

Dilatation of the ureters and renal pelves occurs early in pregnancy up to the 20th week. It results from the effects on the ureteric smooth muscle of high levels of circulating progesterone and is part of normal pregnancy. The ureters return to their normal size within 12 weeks of delivery. This physiological condition is associated with an increased liability to infection and there is a possibility that abdominal pain during pregnancy may be erroneously ascribed to ureteric obstruction (Summary box 75.12).

Summary box 75.12

Ureteric dilatation in pregnancy

- Physiological dilatation of the ureter is common in pregnancy

Imaging

Ultrasound scanning (Figure 75.17) is the least invasive means of detecting hydronephrosis and is regularly used to diagnose pelvicureteric junction obstruction in utero.

IVU helps only if there is significant function in the obstructed kidney. The extrarenal pelvis is dilated and the minor calyces lose their normal cupping and become ‘clubbed’. If the level of obstruction is in doubt, it can help to take follow-up films 36 hours after the contrast has been injected. Contrast slowly diffuses to fill the obstructed system down to the blockage.

Isotope renography is the best test to confirm obstructive dilatation of the collecting system. A substance (usually diethyleneetriaminepenta-acetic acid (DTPA) or MAG-3) is injected intravenously. The DTPA is labelled with technetium-99m, a gamma-ray emitter, so that the passage of 99mTc-labelled DTPA through the kidneys can be tracked using a gamma camera. 99mTc-DTPA is cleared from a normal kidney but stays

Figure 75.17 Ultrasound of a hydronephrotic kidney. A, artery; C, calyces; P, pelvis.
in the renal pelvis on the obstructed side and is retained even if urine flow is increased by administering frusemide (Figure 75.18).

Very occasionally, a Whitaker test is indicated. A percutaneous puncture of the kidney is made and fluid is infused at a constant rate with monitoring of intrapelvic pressure. An abnormal rise in pressure confirms obstruction. Retrograde pyelography (Figure 75.19) is rarely indicated but will confirm the site of obstruction immediately before corrective surgery (Summary box 75.13).

**Summary box 75.13**

**Imaging**
- Obstruction of the ureter is diagnosed by a combination of ultrasound scanning and isotope renography
- An obstructed kidney is worth preserving if it is contributing more than 20 per cent of total renal function

**Treatment**
The indications for operation are bouts of renal pain, increasing hydronephrosis, evidence of parenchymal damage and infection. Nephrectomy should be considered only when the kidney has been largely destroyed. Mild cases should be followed by serial ultrasound scans and operated upon if dilatation is increasing.

**Pyeloplasty**
In the Anderson–Hynes operation (Figure 75.20), the upper third of the ureter and the renal pelvis are mobilised. A renal vein overlying the distended pelvis can be divided, but an artery in this situation should be preserved to avoid infarction of the territory that it supplies. The anastomosis is made in front of such an artery. A nephrostomy tube or a ureteric stent protects the anastomosis. Laparoscopic pyeloplasty is becoming increasingly popular.

**Endoscopic pyelolysis**
Disruption of the pelviureteric junction by a balloon passed up the ureter and distended under radiographic control has been used to treat idiopathic pelviureteric junction obstruction.
The long-term efficacy of this and various forms of endoscopic pyelotomy has still to be proved. The alternative minimal access procedure, laparoscopic pyeloplasty, is increasingly popular.

**RENAral CALCULI**

Aetiology
This subject is complex and the following represents a brief summary of current opinion.

Dietetic
Deficiency of vitamin A causes desquamation of epithelium forming a nidus on which a stone is deposited. This mechanism is probably active in the formation of bladder calculi.

Altered urinary solutes and colloids
Dehydration concentrates urinary solutes until they precipitate. Reduction of urinary colloids, which adsorb solutes, or mucoproteins, which chelate calcium, might tend to crystal and stone formation.

Decreased urinary citrate
The presence of citrate in urine, 300–900 mg per 24 hours (1.6–4.7 mmol per 24 hours) as citric acid, keeps relatively insoluble calcium phosphate and citrate in solution.

Renal infection
Infection favours the formation of urinary calculi. Clinical and experimental stone formation are common when urine is infected with urea-splitting *Proteus* organisms. The calculus may enlarge to fill most of the collecting system, forming a stag-horn calculus (Figure 75.22) even a large stag-horn calculus may be asymptomatic for years until it presents with haematuria, urinary infection or renal failure.

Uric acid and urate calculi
These are hard, smooth and often multiple and multifaceted. Pure uric acid stones are radiolucent. CT will distinguish them from other causes of filling defects including tumours of the ureter. Most uric acid stones contain some calcium, so they cast a faint radiological shadow.

Cystine calculus
An uncommon congenital error of metabolism leads to cystinuria. Cystine stones are often multiple and may grow to form a cast of the collecting system. Cystine stones are radio-opaque and very hard.

Hyperparathyroidism
Hyperparathyroidism leading to hypercalcaemia and hypercalciuria is found in 5 per cent or less of those who present with radio-opaque calculi. In cases of recurrent or multiple stones, this cause should be eliminated by appropriate investigations (see Chapter 51). A parathyroid adenoma should be removed before definitive treatment for the urinary calculi.

Types of renal calculus
Oxalate calculus (calcium oxalate)
Oxalate stones are irregular with sharp projections (Figure 75.21). A calcium oxalate monohydrate stone is hard and radiodense.

Phosphate calculus
A phosphate calculus (calcium phosphate often with ammonium magnesium phosphate (struvite)) is smooth and dirty white. It grows in alkaline urine, especially when urea-splitting *Proteus* organisms are present. The calculus may enlarge to fill most of the collecting system, forming a stag-horn calculus (Figure 75.22). Even a large stag-horn calculus may be asymptomatic for years until it presents with haematuria, urinary infection or renal failure.

Figure 75.21 Oxalate calculi. The larger one removed from the right kidney is blackened by the deposition of altered blood.

**The first nephrolithotomy was performed by Ambrose Paré (1509–1590) on a prisoner condemned to death by hanging. Paré cut out two stones from his kidney following which he was cured. As he recovered from this procedure, he secured remission from his death penalty and was given a grant of money. “I dressed his wounds, but God healed him.”**

Figure 75.22 Stag-horn calculus.

---

Theodor Escherich, 1857–1911, Professor of Paediatrics, Vienna, Austria, discovered the bacterium *coli commune* in 1886.
Clinical features
Renal calculi are common. Approximately 50 per cent of patients present between the ages of 30 and 50 years. The male–female ratio is 4:3 (Summary box 75.14).

Summary box 75.14
Renal stones
- Are common
- May be clinically silent even when large
- Are usually visible on a plain abdominal radiograph
- May be radiolucent when composed of uric acid

Silent calculus
Renal failure may be the first indication of bilateral silent calculi, although secondary infection usually produces symptoms first.

Pain
Pain occurs in 75 per cent of people with urinary stones. Fixed renal pain occurs in the renal angle (Figure 75.23), the hypochondrium, or in both. It may be worse on movement.

Ureteric colic is an agonising pain passing from the loin to the groin. Pain resulting from renal stones rarely lasts more than 8 hours in the absence of infection. There is no pyrexia, although the pulse rate rises because of the severe pain. Ureteric colic is often caused by a stone entering the ureter but it may also occur when a stone becomes lodged in the pelviureteric junction. The severity of the colic is not related to the size of the stone (Summary box 75.15).

Summary box 75.15
Ureteric colic
- Severe exacerbations on a background of continuing pain
- Radiates to the groin, penis, scrotum or labium as the stone progresses down the ureter
- Severity of pain is not related to stone size
- Haematuria is very common
- There may be few physical signs

Abdominal examination
During an attack of ureteric colic, rigidity may be present but not prominent. Percussion over the kidney produces a stab of pain and there may be tenderness on gentle deep palpation. Hydronephrosis or pyonephrosis leading to a palpable loin swelling is rare.

Haematuria
Haematuria, usually small in amount, is common and sometimes is the only symptom of stone disease.

Pyuria
Infection is particularly dangerous when the kidney is obstructed. Pressure builds in the system, organisms are forced into the circulation and a septicemia can quickly develop.

Investigation of suspected urinary stone disease

X-ray
The ‘KUB’ film shows the kidney, ureters and bladder. A branched stone is unmistakable. (Figure 71.24). An opacity maintaining its position relative to the urinary tract during respiration is likely to be a calculus. Calcified mesenteric nodes and opacities within the gut will be anterior to the vertebral bodies on a lateral x-ray and thus outside the urinary tract (Summary box 75.16).

Summary box 75.16
Opacities on a plain abdominal radiograph that may be confused with renal calculus
- Calcified mesenteric lymph node
- Gallstones or concretion in the appendix
- Tablets or foreign bodies in the alimentary canal (e.g. cyclopenthiazide (Navidrex-K))
- Phleboliths – calcification in the walls of veins, especially in the pelvis
- Ossified tip of the 12th rib
- Calcified tuberculous lesion in the kidney
- Calcified adrenal gland

Contrast-enhanced CT
CT, preferably spiral, has become the mainstay of investigation of acute ureteric colic.

Excretion urography
IVU will establish the presence and position of a calculus and the function of the other kidney.

Ultrasound scanning
Ultrasound scanning is of most value in locating stones for treatment by extracorporeal shock wave lithotripsy (ESWL) (see below).
Surgical treatment of urinary calculi

Conservative management

Calculi smaller than 0.5 cm pass spontaneously unless they are impacted. Surgical intervention should be avoided. Small renal calculi may cause symptoms by obstructing a calyx or acting as a focus for secondary infection. Most can be safely observed until they pass (Summary box 75.17).

<table>
<thead>
<tr>
<th>Summary box 75.17</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Management of small stones</strong></td>
</tr>
<tr>
<td>- Most small urinary calculi will pass</td>
</tr>
<tr>
<td>- Infection in an upper urinary tract obstructed by stone is dangerous and needs urgent surgical intervention</td>
</tr>
</tbody>
</table>

Preoperative treatment

Antibiotic treatment starts before surgery and continues afterwards.

Operation for stone

Most stones should be treated by minimal access and minimally invasive techniques. Open operations are still needed when appropriate expertise is not available or newer techniques have failed (Summary box 75.18).

<table>

</tr>
</tbody>
</table>

Modern methods of stone removal

Kidney stones

Percutaneous nephrolithotomy

Endoscopic instruments are passed into the kidney by a percutaneous technique (Figure 75.25). Small stones may be grasped under vision and extracted whole. Larger stones are fragmented by an ultrasound, laser or electrohydraulic probe and removed in pieces.

Figure 75.24 Plain abdominal x-ray showing complete stag-horn calculi.

The aim is to remove all fragments. A nephrostomy drain is left in the system when the procedure is complete. This decompresses the kidney and allows repeated access if necessary. Percutaneous nephrolithotomy is sometimes combined with ESWL in the treatment of complex (stag-horn) calculi.

Complications of percutaneous nephrolithotomy include: (1) haemorrhage from the punctured renal parenchyma; (2) perforation of the collecting system with extravasation of saline irrigant; (3) perforation of the colon or extravasation of saline irrigant during placement of the percutaneous track.

Extracorporeal shock wave lithotripsy

Crystalline stones disintegrate under the impact of shock waves produced by the ESWL machine.

The shocks may be aimed by ultrasound or x-ray imaging (Figure 75.26). The devices also differ in the disruptive force that they can develop. Less powerful machines break stones less effectively and several treatments may be necessary. Weaker shocks hurt less and treatment can be given without general anaesthesia.

Ureteric colic is common after ESWL, and the patient needs analgesia, usually in the form of a non-steroidal anti-inflammatory drug. Bulky stone fragments may impact in the ureter, causing obstruction. To avoid this, a stent should be placed in the ureter to drain the kidney while stone fragments pass. Occasionally, impacted fragments have to be removed ureteroscopically (see below).

The principal complication of ESWL is infection. Many calculi contain bacteria, which are released from the broken stone. It is wise to give prophylactic antibiotics before ESWL, and an obstructed system should be decompressed by a ureteric stent or percutaneous nephrostomy before treatment.

The clearance of stone from the kidney will depend upon the consistency of the stone and its site. Most oxalate and phosphate stones fragment well and, if lying in the renal pelvis, will clear within days. The results with harder stones, especially cystine stones, are less satisfactory. When treating calyceal stones, the patients should be warned that the clearance may take months.

Open surgery for renal calculi

Operations for kidney stone are usually performed via a loin or lumbar approach (Figure 75.27). All of the procedures are difficult unless the kidney is fully mobilised and its vascular pedicle controlled. A sling should be placed around the upper ureter to stop stones migrating downwards.

Pyelolithotomy

Pyelolithotomy is indicated for stones in the renal pelvis. When the wall of the renal pelvis has been dissected from its surrounding fat, an incision is made in its long axis directly on to the stone. The stone is removed with gallstone forceps. Stone fragments in peripheral calyces may be detected by direct palpation or by intraoperative x-ray or nephroscopy. If there is sepsis, a nephrostomy is essential to drain the system.

Extended pyelolithotomy

The plane between the renal sinus and the wall of the collecting system is developed on the posterior surface of the kidney. This avoids major vessels and allows incisions into the calyces so that even large stag-horn stones can be removed intact.
Nephrolithotomy

If there is a complex calculus branching into the most peripheral calyces, it may be necessary to make incisions into the renal parenchyma to clear the kidney. Nephrolithotomy may also be necessary when the adhesions from previous surgery complicate access to the renal pelvis. The renal pedicle is temporarily cross-clamped to reduce bleeding from the vascular renal tissue. Incisions are made posterior and parallel to the most prominent part of the convex renal border, where the territories of the anterior and posterior branches of the renal artery meet (Brödel’s line). Cooling the kidney extends the ischaemia. Nephrolithotomy incisions must be closed with haemostatic sutures and the patient observed for signs of reactionary haemorrhage.

Partial nephrectomy is sometimes preferable for a stone in the lowermost calyx with infective damage to the adjacent parenchyma.

A functionless kidney destroyed by stone disease should be removed, particularly when there is xanthogranulomatous pyelonephritis. This stone-related inflammatory mass must be removed with care because it is liable to be attached to adjacent structures such as the colon.

Treatment of bilateral renal stones

Usually the kidney with better function is treated first, unless the other kidney is more painful or there is pyonephrosis which needs urgent decompression.

Prevention of recurrence

Ideally, stone formers should be investigated to exclude metabolic factors, although the diagnostic yield is low in patients with a single small stone. The urine should be screened for infection. The following investigations are appropriate in bilateral and recurrent stone formers:

- serum calcium, measured fasting on three occasions to exclude hyperparathyroidism;
- serum uric acid;
- urinary urate, calcium and phosphate in a 24-hour collection; the urine should also be screened for cystine;
- analysis of any stone passed.

Dietary advice is not usually helpful in avoiding stone recurrence in people who have a balanced diet. Those who consume excessive amounts of milk products (calcium stones), rhubarb, strawberries, plums, spinach and asparagus (calcium oxalate stones) should be advised to be more moderate.

Patients with hyperuricaemia should avoid red meats, offal and fish, which are rich in purines, and should be treated with allopurinol. Eggs, meat and fish are high in sulphur-containing proteins and should be restricted in cystinuria.

Max Brödel, 1870–1941, medical artist who founded ‘The Department of Art as Applied to Medicine’ at the Johns Hopkins Hospital, Baltimore, MD, USA.
Stone sufferers should drink plenty to keep their urine dilute.

Drug treatment is largely ineffective except in those few patients who are shown to have idiopathic hypercalciuria. Bendroflumethiazide (5 mg) and a calcium-restricted diet reduce urinary calcium (Summary box 75.19).

### Summary box 75.19

**Recurrent stone formation**
- Stones are more common in those who have had a previous stone.
- Unless there is a specific biochemical abnormality, high fluid intake is the best prophylactic measure.

---

**URETERIC CALCULUS**

A stone in the ureter usually comes from the kidney. Most pass spontaneously.

**Clinical features**

A stone passing down the ureter often causes intermittent attacks of ureteric colic.

**Ureteric colic**

The waves of agonising loin pain are typically referred to the groin, external genitalia and the anterior surface of the thigh. As the stone enters the bladder, the pain can be referred to the tip of the penis.

**Impaction**

There are five sites of narrowing where the stone may be arrested (Figure 75.28). An impacted stone causes a more consistent dull pain, often in the iliac fossa and increased by exercise and lessened by rest. Distension of the renal pelvis due to obstruction may cause loin pain. The stone may become embedded as the adjacent ureteric wall becomes eroded and oedematous as a result of pressure ischaemia. Perforation of the ureter and extravasation of urine is a rare complication.

Severe renal pain subsiding after a day or so suggests complete ureteric obstruction. If obstruction persists after 1–2 weeks, the calculus should be removed to avoid pressure atrophy of the renal parenchyma.

**Haematuria**

Almost all ureteric colic is associated with transient microscopic haematuria. Serious bleeding is uncommon and should suggest clot colic.

---

![Figure 75.26](image1) Extracorporeal shock wave lithotripsy. (a) The patient being placed on the ultrasound lithotripter. (b) Positioning of the patient being checked by ultrasound.

![Figure 75.27](image2) Open operations for renal calculus.
Abdominal examination

There is tenderness and some rigidity over some part of the course of the ureter. The presence of haematuria does not rule out appendicitis because an inflamed appendix can give rise to a local ureteritis leaking some red cells into the urine. The patient with acute ureteric colic is usually in greater pain and less ill than one with appendicitis or acute cholecystitis.

Imaging

Most urinary calculi are radio-opaque. Stones are difficult to see if small or obscured by bowel contents or nearby bones. IVU while the patient has pain can confirm the diagnosis, although spiral CT is preferable. In ureteric colic, there will probably be little or no excretion on the affected side. Occasionally, there is an extravasation of contrast from the dilated system. Late x-rays, taken up to 36 hours after the injection of the dilated system, may show dilatation of the ureter down to an obstructing calculus. A radiolucent uric acid stone may be demonstrated as a filling defect in the contrast-filled system.

Analgesic abusers occasionally fake symptoms to obtain drugs, and emergency imaging is useful in excluding renal colic. If the CT or urogram is normal during an attack, the patient does not have renal colic. The absence of blood in the urine makes colic less likely but its presence can be simulated.

Cystoscopy is not indicated routinely but may reveal oedema around the ureteric orifice when the stone is nearby.

Retrograde ureterography is performed as an immediate preliminary to an endoscopic operation to remove a calculus.

Treatment

Pain

Non-steroidal anti-inflammatory drugs, such as diclofenac and indomethacin, have replaced opiates as the first line of treatment for renal colic. The value of smooth muscle relaxants, such as propantheline (Pro-Banthine), is debatable.

Removal of the stone

Expectant treatment is appropriate for small stones likely to pass naturally (Summary box 75.20). If the patient is not disabled by recurrent attacks of colic, progress can be followed by x-rays every 6–8 weeks.

Endoscopic stone removal

Dormia basket

The use of wire baskets under image intensifier control has been replaced by ureteroscopic techniques but they may be useful when the instruments and expertise are not available (Figure 75.29). There is a danger of ureteric injury even with small stones.

Ureteric meatotomy

Endoscopic incision with a diathermy knife will enlarge the opening and free a stone lodged in the intramural ureter. The consequent urinary reflux rarely causes problems.

Ureteroscopic stone removal

A ureteroscope is introduced transurethrally across the bladder into the ureter (Figure 75.30) to remove stones impacted in the

Figure 75.28 Normal anatomical narrowings (1–5) of the ureter.

Figure 75.29 Dormia stone-catching basket in use: (a) basket introduced past stone; (b) opened; and (c) enclosing stone, ready for withdrawal.

Enrico Dormia, 1928–2009, Professor of Urology, University of Milan and Chief of the Department of Urology, S Carlo Hospital, Milan.
ureter. Stones that cannot be caught in baskets or endoscopic forceps under direct vision are fragmented using an electrohydraulic, percussive or laser lithotripter.

**Push bang**
A stone in the middle or upper part of the ureter can often be flushed back into the kidney using a ureteric catheter. A J-stent secures the calculus in the kidney for subsequent treatment with ESWL.

A flexible fibreoptic ureteroscope can be used for laser destruction of calculi in the renal collecting system or ureter and to retrieve small stones from the kidney.

**Lithotripsy in situ**
A stone in a part of the ureter that can be identified by the imaging system of the lithotripter can be fragmented in situ. This form of treatment is not appropriate if there is complete obstruction or if the stone has been impacted for a long time.

**Open surgery**
**Ureterolithotomy**
An x-ray confirms the position of the stone immediately before surgery.

The skin incision must be appropriate for the position of the stone. Calculi in the upper third of the ureter are approached through a loin or upper quadrants transverse incision as used for a stone in the renal pelvis. Access to midureteric stones is through a muscle-cutting iliac fossa incision; lower ureteric stones are best reached through a Pfannenstiel incision. For stones close to the bladder, exposure is improved by ligating and dividing the superior vesical vascular pedicle. The ureter is exposed in the retroperitoneum and slings are applied above and below the calculus to stop it from escaping. The ureter is incised longitudinally, directly on to the stone, which is freed by blunt dissection and removed with stone forceps. Soft catheters are passed upwards and downwards to ensure that the ureter is clear. The ureterotomy is closed with interrupted absorbable sutures and a drain left to drain urine leakage. The operation can be performed laparoscopically, but alternative minimal access techniques described above are usually preferable.

### IDIOPATHIC RETROPERITONEAL FIBROSIS
In this rare condition, one or both ureters are bound in progressive fibrosis of the retroperitoneal tissues. Most cases are idiopathic but some may be drug related. A similar clinical picture occurs in patients with leaking aortic aneurysm and infiltrating retroperitoneal malignancy.

The patient complains of persistent backache. The onset of anuria and renal failure prompts investigation of the renal tract, which reveals hydronephrosis. The IVU typically shows medial displacement of the ureters and the CT appearances are diagnostic. The sedimentation rate is markedly raised.

**Treatment**
It may be possible to insert temporary ureteric stents while renal function recovers. If not, percutaneous nephrostomies will drain the obstructed kidneys. Some patients need dialysis. Some advocate conservative treatment with steroids. Surgery involves dissection of the ureters from their fibrous jacket (ureterolysis). Wrapping omentum around the freed ureters discourages recurrent obstruction.

### KIDNEY INFECTIONS

#### Aetiology
Renal infections arise in the following ways (Summary box 75.21):

- **Haematogenous infection** from a primary site in the tonsils or carious teeth or from cutaneous infections, particularly boils or a carbuncle. Renal tuberculosis occurs by bloodborne spread from lymph nodes in the neck, chest or abdomen.
- **Ascending infection** in the urinary tract is the most common route, and it is most likely to occur when there is vesicoureteric reflux. Urinary stasis and the presence of calculi are common contributory factors.

#### Bacteriology
*Escherichia coli* and other Gram-negative organisms are commonly responsible. In *E. coli* and streptococcal infections, the urine is acidic. *Proteus* spp. and staphylococci split urea to form ammonia, which makes the urine alkaline and promotes the formation of calculi.

---

**Figure 75.30 Ureteroscopy.** X-ray showing a ureteroscope and guidewire in the lower ureter.
Kidney infection

- Acute pyelonephritis:
  - In childhood
  - In pregnancy
  - With urinary obstruction
- Chronic pyelonephritis:
  - Reflux nephropathy
  - Pyonephrosis
  - Renal abscess
  - Perinephric abscess

Acute pyelonephritis

Acute pyelonephritis is more common in females, especially during childhood, at puberty, after intercourse, during pregnancy and during menopause. It occurs more on the right and is frequently bilateral.

Clinical features

There may be prodromal headache, lassitude and nausea, but the onset of pain is usually sudden, often with a rigor and vomiting. There is acute pain in the flank and hypochondrium. The remitting temperature rises to 39°C or more. The symptoms of cystitis commonly set in, with urgency, frequency and scalding dysuria. There is tenderness in the hypochondrium and in the loin. Rarely, in cases of severe bilateral pyelonephritis, especially when there is an associated obstruction, renal dysfunction may be sufficient to cause uraemia. The risk of life-threatening septicaemia is ever present (Summary box 75.22).

Bacteriological examination of the urine

A midstream urine specimen should be collected into a sterile container; the urine is centrifuged and the sediment examined microscopically. In early acute pyelonephritis, there are usually pus cells and many bacteria. The urine may be misleadingly clear to the eye until the infection becomes established. Culture and sensitivity testing of the causative organisms allows a rational choice of antibiotic, but parenteral treatment with a broad-spectrum antibiotic should be started before the results are available.

Severe cases

There are rigors and a temperature of 40°C or more, often without a corresponding tachycardia. There is vomiting, sweating and thirst; the patient feels awful. Blood culture is usually positive, especially if the specimen has been taken during a rigor.

Differential diagnosis

It may be difficult to be sure that the patient does not have pneumonia, acute appendicitis or acute cholecystitis. The urgent need is to distinguish acute pyelonephritis from appendicitis, and the site of pain and the presence of marked peritonism are usually helpful. A plain abdominal x-ray may show the outline of a swollen kidney and, if the infection is severe, an ultrasonographer may confirm the appearance of pyelonephritis.

Special cases

Pyelonephritis of pregnancy

Pyelonephritis of pregnancy usually occurs between the fourth and sixth months of gestation in women with a past history of recurrent urinary infection. In about 10 per cent of cases, the disease runs a severe and protracted course and occasionally leads to abortion or premature birth.

Urinary infection in childhood

Urinary infection in childhood may damage the growing kidney. In young children, symptoms are often non-specific but the child may pass cloudy or offensive urine. The possibility of urinary sepsis should be considered if a child fails to thrive or suffers unexplained pyrexia. Pain or screaming on micturition may occur. The older child may complain of loin pain and may develop urinary frequency and secondary enuresis.

Up to 50 per cent of children with urinary infection have an underlying anatomical abnormality (e.g. reflux or obstruction). The diagnosis of infection is confirmed by examination of a clean-catch specimen or a specimen obtained by suprapubic needle puncture. On culture, a pure growth of more than $10^5$ organisms/mL with a significant pyuria is evidence of infection. Such children should be investigated for underlying urinary tract abnormalities and to assess renal function and scarring.

Vesicoureteric reflux of urine is detectable in about 35 per cent of children with recurrent urinary infection. Renal damage results from the combination of reflux and urinary infection early in life, and reflux nephropathy is a common cause of end-stage renal failure in the UK. Long-term prophylactic antibiotic treatment has become the favoured treatment for recurrent urinary infections resulting from reflux. Surgical reimplantation of the ureters is reserved for those in whom conservative measures fail. However, reimplantation in these patients may fail to cure reflux (Summary box 75.23).

Acute pyelonephritis associated with urinary retention

Acute pyelonephritis is a relatively uncommon complication of chronic urinary retention. Often the organisms are introduced...
during instrumentation. Patients with a significant postmicturition urinary residue need prophylactic antibiotics to cover transurethral procedures.

**Treatment**

The treatment of acute pyelonephritis should be prompt, appropriate and prolonged. Investigation to exclude underlying abnormalities in the urinary tract should be undertaken when the acute illness subsides.

While awaiting the bacteriological report and the results of sensitivity tests, a broad-spectrum antibiotic, such as amoxicillin or gentamicin, should be administered, parenterally if necessary. When pain is severe, a morphine-like analgesic drug may be necessary if non-steroidal anti-inflammatory agents are ineffective. The patient should drink copiously; if this is not possible because of nausea and vomiting, an intravenous infusion should be set up.

Most urinary infections acquired outside hospital are sensitive to agents such as trimethoprim and amoxicillin. Hospital-acquired infections are much more likely to be resistant and second-line antibiotics may be needed. Gentamicin and carbencillin are suitable for infections with more resistant strains of *Pseudomonas pyocyanea*, *Proteus* spp. and *Klebsiella* spp. Ciprofloxacin is particularly useful against *Pseudomonas* spp. in patients who do not have septicemia. Despite the efficacy of modern antibacterial drugs, recurrent infection is likely if there is an untreated underlying abnormality of the urinary tract such as a stone, vesicoureteric reflux, fistula to the gastrointestinal tract or retention of urine.

**Chronic pyelonephritis**

Chronic pyelonephritis is often associated with vesicoureteric reflux, sometimes called ‘reflux nephropathy’, is an important cause of renal damage and end-stage renal failure.

**Pathology**

There is interstitial inflammation and scarring of the renal parenchyma with a patchy distribution.

**Clinical features**

The condition is almost three times as common in women as it is in men. Two-thirds of female patients are under 40 years of age, whereas 60 per cent of male patients are over 40.

It is possible, but unusual, for chronic pyelonephritis to remain clinically silent until the symptoms of advanced renal insufficiency appear.

Lumbar pain, dull and non-specific in character, is present in 60 per cent of cases. Increased urinary frequency and dysuria are common. Hypertension, present in 40 per cent of cases, may be of the accelerated (‘malignant’) type. Tiredness, malaise, anorexia, nausea and headache constitute the main complaint in 30 per cent of cases. The true cause of these nonspecific symptoms may elude diagnosis for years.

Normochromic anaemia due to unsuspected renal impairment is an occasional presenting feature (Summary box 75.24).

**Investigations**

The glomeruli are relatively preserved so proteinuria is less marked than in glomerulonephritis (<3 g daily). Casts are not usually present but white cells are plentiful.

---

**Summary box 75.24**

**Chronic pyelonephritis**

- A common cause of end-stage renal failure
- Often associated with ureteric reflux
- May be symptomatically silent
- Leads to progressive renal scarring

*Escherichia coli, Streptococcus faecalis, Proteus* spp. or *Pseudomonas* spp. are found in the urine.

**Treatment**

Treatment aims at eradicating predisposing factors such as obstruction or stones and treating the infection, often with repeated courses of antibiotic. Scarred parenchyma is vulnerable to blood-borne organisms and reinfection is likely. Consequently, antibiotics confer only temporary benefit and progressive renal damage is common.

Surgery is indicated only when the disease is confined to one kidney. This is unusual but in such cases nephrectomy or partial nephrectomy may stop the symptoms of infection and make hypertension easier to control. Patients with end-stage renal failure require renal replacement therapy.

**Pyonephrosis**

Pyonephrosis results from infection of a hydronephrosis, follows acute pyelonephritis or, most commonly, arises as a complication of renal calculus disease. The kidney becomes a multilocular sac containing pus or purulent urine.

**Clinical features**

The classical triad of symptoms is anaemia, fever and a swelling in the loin. When the condition arises as an infected hydronephrosis, the swelling may be very large and the pyrexia very high and associated with rigors. Symptoms of cystitis may be prominent.

**Investigations**

Imaging may show a calculus and will demonstrate dilatation of the pus-filled collecting system.

**Treatment**

Pyonephrosis is a surgical emergency because permanent renal damage and lethal septicaemia threaten. Parenteral antibiotics should be given and the kidney drained. If the pus is too thick to be aspirated through a large percutaneous nephrostomy, consider open nephrostomy. When there is a stone, it should be removed. Nephrectomy may be appropriate when the kidney is destroyed and function on the other side is good.

**Renal carbuncle**

An abscess may form in the renal parenchyma as the result of blood-borne spread of organisms, especially coliforms or *Staphylococcus aureus*. Renal carbuncle is most commonly seen in diabetics, intravenous drug abusers, those debilitated by chronic disease and patients with acquired immunodeficiency.

**Pathology**

The renal parenchyma contains an encapsulated necrotic mass.
Clinical features
There is an ill-defined tender swelling in the loin, persistent pyrexia and leukocytosis, simulating a perinephric abscess. Initially there is no pus or bacteria in the urine, but these appear later. The mass in the kidney may be confused with a renal adenocarcinoma (Figure 75.31).

Treatment
Resolution by antibiotic treatment alone is unusual. Formal open incision of the abscess may be necessary if the pus is too thick to be drained by percutaneous aspiration.

Perinephric abscess
The common causes of perinephric abscess are shown in Figure 75.32. Other causes are infection of a perirenal haematoma and perinephric discharge of an untreated pyonephrosis or renal carbuncle. A mycobacterial perinephric abscess may arise by extension from a nearby tuberculous vertebra.

Clinical features
There is swinging pyrexia, abdominal tenderness and fullness in the loin (Figure 75.33). Local signs present early if the infection starts in the lower part of the perinephric fat. Infection at the upper pole is masked by the lower ribs and signs in the loin are less. The white cell count is always markedly raised but there are characteristically no pus cells or organisms in the urine.

Imaging
Ultrasonography and CT are diagnostic.

Treatment
Open drainage may be necessary if the abscess cannot be aspirated through a percutaneous needle. A lumbar incision is made under antibiotic cover large enough to allow the surgeon to open pockets of pus and to explore for an unruptured cortical abscess. Pus is sent for culture and the wound is closed over a tube drain (Summary box 75.25).

Summary box 75.25

Management of perinephric abscess
- Collections of pus in or around the kidney should be drained

Renal tuberculosis

Aetiology and pathology
Tuberculosis of the urinary tract arises from haematogenous infection from a distant focus. The lesions are usually unilateral. Tuberculous granulomas in a renal pyramid coalesce to form an ulcer. Mycobacteria and pus cells discharge into the urine. Untreated lesions enlarge and a tuberculous abscess may form in the parenchyma. The necks of the calyces and the renal pelvis stenosed by fibrosis confine the infection so that there is tuberculous pyonephrosis, sometimes localised to one pole of the kidney. Extension of pyonephrosis or tuberculous renal abscess leads to perinephric abscess and the kidney is progressively replaced by caseous material (putty kidney), which may
be calcified (cement kidney). At any stage, the plain x-ray may show areas of calcification (pseudocalculi). Less commonly, the kidneys may be bilaterally affected as part of the generalised process of miliary tuberculosis (Figure 75.34).

Renal tuberculosis is often associated with tuberculosis of the bladder and typical tuberculous granulomas may be visible in the bladder wall. In men, tuberculous epididymo-orchitis may occur without apparent infection of the bladder.

**Clinical features**

Renal tuberculosis usually occurs between 20 and 40 years of age, and is more common in men than women.

Urinary frequency is often the earliest symptom and may be the only one. The patient complains of a progressive increase in both daytime and night-time frequency.

‘Sterile’ pyuria

Routine urine culture is negative but there are white cells in the urine.

**Pain**

Painful micturition is a feature of tuberculous cystitis. First, there is a suprapubic pain if voiding is delayed; later, a burning pain accompanies micturition. When there is secondary infection, a superadded agonising pain referred to the tip of the penis or to the vulva is often associated with haematuria and strangury.

Renal pain is often minimal but there may be a dull ache in the loin.

**Haematuria**

In 5 per cent of cases, the first symptom is haematuria occurring from an ulcer on a renal papilla. The tuberculous lesion may be difficult to detect radiologically and mycobacteria may not be cultured from the urine until months later.

A tuberculous kidney is oedematous and friable and is more liable to damage than a normal kidney.

Malaise and weight loss are usual and a low-level evening pyrexia is typical. A high temperature suggests secondary infection or dissemination, i.e. miliary tuberculosis.

**On examination**

It is unusual for a tuberculous kidney to be palpable. The prostate, seminal vesicles, vasa and scrotal contents should be examined for nodules or thickening (Summary box 75.26).

*Summary box 75.26*

**Renal tuberculosis**

- Consider when symptoms of cystitis continue despite treatment with antibiotics
- Is a cause of ‘sterile pyuria’
- Causes chronic inflammation and scarring throughout the urinary tract, which may continue after antituberculous treatment has been instituted
- May cause obstructive lesions throughout the urinary tract

**Investigation**

**Bacteriological**

Three complete specimens of early-morning urine should be sent for microscopy and culture before specific chemotherapy is started. Staining of the urine sediment with the Ziehl–Neelsen stain occasionally shows the presence of acid-fast bacilli, but proof that these are pathological mycobacteria must await culture on Löwenstein–Jensen medium. When the clinical picture is convincing, it is permissible to start anti-tuberculous therapy in anticipation of the culture results some 6 weeks later.

**X-ray**

An abdominal x-ray may show calcified lesions.

**Intravenous urography**

Early in the disease, the clear-cut outline of a renal papilla may be rendered indistinct by the presence of ulceration. Later, there may be calyceal stenosis (Figure 75.35) and/or hydronephrosis caused by stricture of the renal pelvis or the ureter draining the affected kidney (Figure 75.36). A tuberculous abscess appears

---

**Figure 75.34** Types of lesion in renal tuberculosis.
as a space-occupying renal lesion. The bladder may appear shrunken, with its wall irregular or thickened.

**Cystoscopy**

Cystoscopy is not routine in the investigation of urinary tuberculosis but is often performed because there has been haematuria or unexplained bladder symptoms. The tuberculous urothelium is studded with granulomas that cluster particularly around the ureteric orifices, sometimes with ulceration. As the bladder wall fibroses, the bladder capacity decreases. Contraction of the fibrosed ureter tugs at the ureteric orifice, which is displaced upwards, its mouth wide open (the so-called 'golf-hole' orifice).

**Chest x-ray**

A chest x-ray will exclude an active lung lesion.

**Treatment**

Anti-tuberculous chemotherapy is best managed by a specialist. The surgeon must ensure that the state of the urinary tract is reviewed during the first few weeks of therapy because scarring and stenosis continue after treatment has started.

Prognosis in renal tuberculosis is good if the patient completes the course of chemotherapy.

**Operative treatment**

Operative treatment should be conservative, aiming to remove large foci of infection, which are difficult to treat with drugs, and correct the obstruction caused by fibrosis. The optimum time for surgery is between 6 and 12 weeks after the start of anti-tuberculous chemotherapy.

A repertoire of procedures is needed to deal with various potential effects of urinary tuberculosis. An obstructed lower pole calyx may be drained into the upper ureter. A strictured renal pelvis needs a pyeloplasty. Ureteric stenosis and shortening may require a Boari operation or a bowel interposition, depending on the level and extent of the fibrosis. If the kidney has no function it is best to perform a nephroureterectomy (Figure 75.37). A badly contracted bladder may be replaced with a neobladder fashioned from a loop of bowel in a substitution cystoplasty.

**NEOPLASMS OF THE KIDNEY**

Neoplasms of the kidney are summarised in Summary box 75.27.

**Summary box 75.27**

<table>
<thead>
<tr>
<th>Renal neoplasms</th>

</tr>
<tr>
<td>Squamous cell carcinoma of the renal pelvis</td>
</tr>
</tbody>
</table>

**Benign neoplasms**

**Adenoma**

Pea-like cortical adenomas are occasionally discovered. They are asymptomatic and are benign.

**Angioma**

Angioma may cause profuse haematuria, often in young adults. The bleeding source may be difficult to diagnose without renal angiography.

**Angiomyolipoma**

Angiomyolipoma is an unusual tumour of the kidney often but not always associated with tuberous sclerosis. Its high fat
content has a typical appearance on CT. Malignant elements are present in about one-quarter and may metastasise.

**Malignant neoplasms**

**Renal neoplasm in children**

**Wilms’ tumour (synonym: nephroblastoma)**

This mixed tumour contains elements from embryonic nephrogenic tissue (Figure 75.38). Nephroblastoma is usually discovered during the first five years of life, usually in one pole of one kidney. Bilateral tumours pose a difficult problem.

**Pathology**

A rapidly growing tumour is likely to be friable in consistency.

**Clinical features**

An abdominal tumour grows rapidly in a poorly child. The mass may be very large. Some patients are hypertensive.

Haematuria is an unfavourable symptom denoting extension of the tumour into the renal pelvis.

Imaging confirms a solid space-occupying lesion in the kidney, with or without venous invasion, contralateral disease and distant spread.

Metastasis to the lungs occurs early. Liver, bone and brain metastases are rare. Lymphatic spread is uncommon.

**Treatment**

These children are best treated in specialist paediatric oncology units. Most unilateral tumours are treated by chemotherapy followed by nephrectomy. Partial nephrectomy may be possible in patients with bilateral disease.

**Prognosis**

Eighty per cent survive long term with modern chemotherapy and surgery. The prognosis is worse in those with metastases and in older children (Summary box 75.28).

**Renal neoplasm in adults**

**Hypernephroma (synonym: Grawitz’s tumour)**

This adenocarcinoma, the most common neoplasm of the kidney (75 per cent incidence), arises from renal tubular cells.

**Pathology**

The cut surface is usually yellowish or dull white, semi-transparent, with areas of haemorrhage (Figure 75.39). The tumour is often divided into lobules, some of which are cystic. Larger tumours are irregular in shape with central haemorrhage and necrosis.

**Microscopic structure**

The most common pattern is of solid areas of polyhedral or cubical clear cells with deeply stained, small, rounded nuclei and abundant cytoplasm containing lipids, cholesterol and glycogen. The cells are occasionally arranged as papillary cysts or tubules. Less commonly, the cells are granular (dark), and both clear and dark cells may be represented in the same tumour. The scanty stroma is richly vascular.

**Spread**

The tumour is prone to grow into the renal vein. Cells enter the circulation and reach the lungs, where they grow to form can-
nonball secondary deposits (Figure 75.40). Metastasis to bone also occurs and a secondary deposit in a long bone may be the only sign of distant spread for a year or more. Highly vascular metastases may pulsate. Tumour extending beyond the renal capsule is liable to metastasise via the lymph nodes in the hilum of the kidney to the para-aortic nodes and beyond.

Clinical features
Adenocarcinoma of the kidney is more common in men. Haematuria is usually the presenting symptom, sometimes with clot colic. There may be a dragging discomfort in the loin or the patient may detect a mass. In men, a rapidly developing varicocele is a rare but impressive sign, most often on the left side because the left gonadal vein is obstructed where it joins the left renal vein.

Atypical presentations
In 25 per cent of cases there are no local symptoms. The patient presents with symptomatic secondary deposits in bone (Figure 75.41) or the lung (persistent cough or haemoptysis).

Occasionally, persistent pyrexia (37.8–38.9°C) with no evidence of infection is the only symptom. Pyrexia after nephrectomy suggests metastases.

A few patients present with constitutional symptoms and anaemia.
Polycythaemia occurs in 4 per cent of cases as a result of the production of erythropoietin by tumour cells. The erythrocyte sedimentation rate is always raised above the 1–2 mm found in idiopathic polycythaemia vera. The blood count returns to normal after nephrectomy unless there are metastases. Other hormones, such as renin and calcitonin, may be produced by the tumour. Hypercalcaemia is common.

Nephrotic syndrome has been reported as a rare presentation of hypernephroma.

Investigation
IVU is being supplanted by CT in the investigation of haematuria. There is typically abnormal calcification and distortion of the renal outline. The calyces may be stretched and distorted. It is important to know whether the contralateral kidney is working (Figure 75.42). CT with enhancement will demonstrate the extent of the lesion and will show whether the hilar lymph nodes or renal vein are involved (Figure 75.43).

Enthusiasm for renal angiography and preoperative embolisation has waned. Occasionally, a flush inferior cava shows the extent of caval involvement by tumour growing in from the renal vein.

A chest x-ray is essential to detect lung secondaries. An isotope bone scan will reveal deposits in bone.
Treatment

Nephrectomy can be performed through a loin or a transverse or oblique upper abdominal incision. The transabdominal approach has the advantage that the renal pedicle and the inferior vena cava can be widely exposed.

The vascular pedicle should be ligated before the kidney is mobilised because handling the tumour may cause malignant cells to be released into the circulation. The first step in the procedure is to ligate the renal artery in continuity. Once the artery is occluded, the tumour loses most of its profuse blood supply and massive bleeding during mobilisation becomes less likely. Gentle palpation of the renal vein ensures that there is no tumour in its lumen. An empty vein can be divided between ligatures. The renal artery is then divided and the kidney mobilised within its coverings. Aberrant vessels feeding the tumour must be ligated or coagulated to avoid troublesome bleeding. The ureter is then traced downwards as far as is safe, tied and divided.

If the renal vein or the inferior vena cava is invaded, the surgeon must obtain early control of the cava above and below the tumour extension. If there is extension into the thorax, the cardiac team may be needed to put the patient on cardiac bypass so that tumour can, if necessary, be removed from the right side of the heart.

Renal adenocarcinoma responds poorly to radiotherapy or conventional chemotherapy. There have been early promising results from clinical trials of the cytokine interleukin-2 in this condition.

Prognosis

Removal of even a large neoplasm may be curative. In operable cases, 70 per cent of patients are well after three years and 60 per cent after five years. Macroscopic involvement of the renal vein or its tributaries, invasion beyond the capsule and lymphatic involvement all worsen the prognosis (Summary box 75.29).

Neoplasms of the kidney

PART 12 | GENITOURINARY

**Summary box 75.29**

**Adenocarcinoma of the kidney**
- Often presents with haematuria
- May be associated with pyrexia of unknown origin, polycythaemia, hypercalcaemia, anaemia and other paraneoplastic symptoms
- Metastasises via the bloodstream to bone, liver and lung (cannonball secondaries)
- Renal vein extension may embolise to the pulmonary circulation during nephrectomy

Papillary transitional cell tumours of the renal pelvis
These resemble those of the bladder but are much less common (Figure 75.44). They may invade the renal parenchyma, be multifocal and metastasise. Multiple ureteric tumours are thought to arise from a field change that predisposes the whole urothelium to metaplasia rather than seeding down the ureter. Whether the carcinogen is chemical or viral is uncertain.

**Clinical features**
Haematuria is the most common clinical symptom.

The presence of malignant cells in the urine may indicate whether the tumour is well or poorly differentiated. There is some evidence that those with poorly differentiated tumours do better if they have preoperative radiotherapy. It is therefore useful to obtain cells from the tumour by sampling using a brush or catheter passed up the ureter under radiological control.

Intravenous urography usually demonstrates the tumour (Figure 75.45). Retrograde pyelography may be helpful if the urogram is indistinct.

**Treatment**
Conventional surgical treatment is by nephroureterectomy. The ureter must be disconnected with a cuff of bladder wall. If this is done by open surgery a second incision is needed to remove the kidney. Alternatively, the ureteric orifice can be widely resected with a resectoscope and the ureter delivered by blunt dissection from the upper abdominal wound used to remove the kidney. Some urologists argue that well-differentiated upper urinary tract transitional tumours should be treated conservatively by resection with appropriate steps taken to avoid the growth of tumour seeded in the percutaneous track.

**Squamous cell carcinoma of the renal pelvis**
This is rare and often associated with chronic inflammation and leucoplaikia resulting from stone. The tumours are radiosensitive but metastasise early and the prognosis is poor.

**Transitional cell tumours of the ureter**
These are rare and behave like tumours of the renal pelvis. Treatment is by nephroureterectomy.

About half of patients with tumours of the upper urinary tract will have tumours in the bladder at some stage. Follow up by cystoscopy with regular urography is therefore necessary to detect recurrent tumours.

**Balkan nephropathy**
Transitional cell tumours of the upper urinary tract have a very high incidence in certain areas of the Balkans. The same population has a high incidence of a form of primary nephropathy. The causative agent has not been identified with certainty but there seems to be an association with the consumption of grain products stored in a damp environment. Tumours that develop against a background of Balkan nephropathy should be treated by nephron-sparing surgery in view of the impaired overall renal function.

---

The Balkans are the countries of the southeast of Europe. They lie south of the Danube and Sava rivers, and form a peninsula bounded on the east by the Aegean and Black Seas, on the west by the Adriatic and Ionian Seas, and on the south by the Mediterranean.
Nephrectomy for benign disease

Nephrectomy is now rarely performed for benign disease except when the kidney is atrophic or dysplastic or the cause of accelerated hypertension. Non-functioning kidneys resulting from longstanding obstruction or stone disease are a potential site for infection and even malignancy. In a simple nephrectomy, the kidney is dissected free through the convenient plane between the capsule and its fatty coverings. If this plane is obscured by the scarring of previous surgery, a subcapsular nephrectomy may be safer.

Laparoscopic renal surgery

The benefits of laparoscopy are being progressively applied to the whole range of renal surgery. Laparoscopic nephrectomy is certainly possible for small kidneys destroyed by benign disease. The technique requires special skills and the full costs and benefits are under evaluation. More complex techniques are necessary when there is bulky excised tissue to be extracted. Laparoscopic surgery for pyeloplasty, ureterolysis and nephrectomy for renal malignancy have all been described.

Hypertension and a unilateral renal lesion

Ischaemia of the renal parenchyma leads to the release of pressor agents that cause arterial hypertension. When a renal lesion is discovered during the investigation of hypertension, nephrectomy may make the hypertension more amenable to drug treatment.

The urinary bladder

CHAPTER

LEARNING OBJECTIVES

To understand:
- The anatomy, vascular supply and innervation of the bladder in relation to function and disease
- The principles of management of bladder trauma, incontinence and fistulae
- The common causes of acute and chronic urinary retention and management
- The different types of bladder cancer and the principles of management

SURGICAL ANATOMY OF THE BLADDER

- It is lined by transitional epithelium covering the connective tissue lamina propria, which contains a rich plexus of vessels and lymphatics.
- When the detrusor muscle hypertrophies, the inner layer, covered by urothelium, stands out, resulting in the appearance of trabeculation.
- Over the trigone is a thin layer of smooth muscle to which the epithelium is closely adherent and which extends as a sheath around the lower ureters and into the proximal urethra.
- Around the male bladder neck is the smooth muscle internal sphincter innervated by adrenergic fibres, which prevents retrograde ejaculation.
- The distal urethral sphincter is a horseshoe-shaped mass of striated muscle that lies anterior and distal to the prostate, or in the proximal two-thirds of the female urethra. It is distinct from the pelvic floor and is supplied by S2–S4 fibres via the pudendal nerve and by somatic fibres passing through the inferior hypogastric plexus.

Fascial and ligamentous supports of the bladder

At the posterolateral bladder neck, condensations of fascia pass forward medially and laterally to the ureter to join with the prostatic fascia; this fascia needs to be divided during cystectomy. The puboprostatic ligaments are well-defined condensations of the anterior endopelvic fascia; they stretch from the front of the prostate to the peritoneum of the pubis and lie lateral to the dorsal vein complex. The urachus and obliterated hypogastric arteries, together with the folds of peritoneum overlying them, are called the median and lateral umbilical ligaments. Condensations of fascia also occur around the superior and inferior vascular pedicles.

Arteries

The superior and inferior vesical arteries are derived from the anterior trunk of the internal iliac artery. Branches from the obturator and inferior gluteal arteries (and from the uterine and vaginal arteries in females) also help to supply the bladder.

Veins

The veins form a plexus on the lateral and inferior surfaces of the bladder. In the male, the prostatic plexus is continuous with the vesical plexus, which drains into the internal iliac vein. In the female, similar large veins are continuous with the vaginal plexus.

Lymphatics

These accompany the veins and drain to nodes along the internal iliac vessels and then to the obturator and external iliac chains. Some lymphatics pass to nodes that are situated posteriorly to the internal iliac artery (hypogastric nodes).

INNERVATION

The parasympathetic input

This is derived from the anterior primary divisions of the second, third and fourth sacral segments (mainly S2 and S3). Fibres pass through the pelvic splanchnic nerves to the inferior hypogastric plexus, from where they are distributed to the bladder (Figure 76.1). The pelvic plexus can be damaged during deep pelvic operations.

The sympathetic input

This arises in the 11th thoracic to the second lumbar segments; fibres pass via the presacral hypogastric nerve (rather than via the sympathetic chains) to the inferior hypogastric plexus.

Somatic innervation

A somatic innervation passes to the distal sphincter mechanism via the pudendal nerves and also via fibres that pass through the inferior hypogastric plexus.
1310 THE URINARY BLADDER

CONGENITAL DEFECTS OF THE BLADDER

Bladder extrophy

Clinical features
Bladder extrophy occurs in 1:50,000 births (male–female ratio 4:1) (Figure 76.2). In the male, the penis is broad and short, and bilateral inguinal herniae may be present. There is separation of the pubic bones (Figure 76.3). In epispadias alone, the pubes are united and external genitalia are almost normal, although in the female the clitoris is bifid (Figure 76.4).

Treatment
The bladder is closed in the first year of life, usually following osteotomy of both iliac bones just lateral to the sacroiliac joints. Later, reconstruction of the bladder neck and sphincters is required. In some patients the reconstructed bladder remains small and requires augmentation. One-stage reconstruction is being practised in some major centres.

Less satisfactorily, urinary diversion can be carried out by means of ureterosigmoid anastomosis, an ileal or colonic conduit, or continent urinary diversion. Long-term complications include: (1) stricture at the site of anastomosis with bilateral hydronephrosis and infection; (2) hyperchloraemic acidosis; and (3) an increased (20-fold) risk of tumour formation (adenoma and adenocarcinoma) at the site of a ureterocolic anastomosis.
**BLADDER TRAUMA**

**Bladder rupture**
This can be intraperitoneal (20 per cent) or extraperitoneal (80 per cent) (Figures 76.5 and 76.6). Intraperitoneal rupture is usually secondary to a blow or fall on a distended bladder, more rarely to surgical damage. Extraperitoneal rupture is caused by blunt trauma or surgical damage. Gross haematuria can be absent. It may be difficult to distinguish extraperitoneal rupture from rupture of the membranous urethra (see Chapter 78). Intraperitoneal rupture is associated with sudden severe pain in the hypogastrium, often accompanied by syncope. The shock subsides and the abdomen distends and there is no desire to micturate. Peritonitis does not follow immediately if the urine is sterile; varying degrees of rigidity are present on examination.

**Investigation**
Computed tomography (CT) is ideal. Plain erect x-rays may show a ground-glass appearance (fluid). Intravenous urography (IVU) may confirm a leak. Retrograde cystography will confirm the diagnosis (Figure 76.7). It is important to image the patient after drainage of contrast as the full bladder may mask extravasation (Summary box 76.1).

</tr>
<tr>
<td>■ May be diagnosed by retrograde cystography</td>
</tr>
</tbody>
</table>

**Treatment of intraperitoneal rupture**
A lower midline laparotomy should be performed; the edges of the rent are trimmed and sutured with a single-layer 2/0 absorbable suture. A suprapubic and a urethral catheter are placed. Very rarely, the rupture will be through an unsuspected tumour; a biopsy can be taken before suturing the defect. Laparoscopic approaches are also now being used.

**Injury to the bladder during operation**
The bladder may be injured in: (1) inguinal or femoral herniotomy; (2) hysterectomy; and (3) excision of the rectum. If the injury is recognised, the bladder must be repaired and catheter drainage maintained for 7 days. If it is not recognised, the treatment is similar to that of rupture of the bladder.

When accidental extraperitoneal perforation of the bladder occurs during endoscopic resection, drainage of the bladder with a urethral catheter and the administration of antibiotics usually suffice. If a mass of extravasated fluid is present it is best to place a small drain through a stab incision. A laparotomy will usually be required if an intraperitoneal perforation is caused by transurethral resection (Summary box 76.2).

RETENTION OF URINE

Acute retention
There are many possible causes of acute retention of urine (see also Chapter 77) (Summary box 76.3).

Summary box 76.3
The most frequent causes of acute retention
Male
- Bladder outlet obstruction (the commonest cause)
- Urethral stricture
- Acute urethritis or prostatitis
- Phimosis
Female
- Retroverted gravid uterus
- Bladder neck obstruction (rare)
Both
- Blood clot
- Urethral calculus
- Rupture of the urethra
- Neurogenic (injury or disease of the spinal cord)
- Smooth muscle cell dysfunction associated with ageing
- Faecal impaction
- Anal pain (haemorrhoidectomy)
- Intensive postoperative analgesic treatment
- Some drugs
- Spinal anaesthesia

Clinical features
- No urine is passed for several hours.
- Pain is present.
- The bladder is visible, palpable, tender (Figure 76.8) and dull to percussion.
- Potential neurological causes should be excluded by checking reflexes in the lower limbs and perianal sensation.

Treatment
Treatment is to pass a fine urethral catheter (14F – French gauge is defined as the circumference in millimetres) and arrange urological management. Occasionally, in postoperative retention a warm bath can help (Figures 76.9, 76.10, 76.11 and 76.12).

Figure 76.8 Distended bladder in a man who presented with retention of urine.

Figure 76.9 Cleaning of the penis before catheterisation.

Figure 76.10 Insertion of local anaesthetic before insertion of a catheter.

Figure 76.11 The use of a penile clamp to ensure that sufficient time is given to allow the anaesthetic to work before the catheter is inserted.
Following a thorough hand wash, sterile gloves are donned. The genitalia are cleaned using soapy antiseptic. Lignocaine gel is inserted into the urethra, warning the patient that this may create stinging. The jelly should be massaged posteriorly in an attempt to anaesthetise the sphincter region, and it is of advantage to place a penile clamp for several minutes. A small Foley catheter should be passed while the penis is held taut. In a female patient, the labia should be parted using the middle and index fingers of the left hand, which should not be moved once cleaning has been performed. Providing a stricture is not the cause, the catheter should pass freely. Once urine begins to drain, it is wise to pass a few more centimetres of catheter into the bladder before the balloon is inflated to avoid inflation in the prostate. Force must not be used (Summary box 76.4).

**Summary box 76.4**

**Catheterisation for acute retention of urine**

Following catheterisation:
- Record the volume of urine drained
- Examine the abdomen to exclude other pathology (rupture of an aortic aneurysm, ureteric colic or diverticulitis can cause confusion)

If the catheter will not pass, it is usually due to poor technique, lack of anaesthesia, traumatisation of the urethra or a urethral stricture. Occasionally, a large prostatic middle lobe may prevent the catheter entering the bladder; sometimes a coudé catheter will pass. If a catheter cannot be passed the following plan should be pursued.

**Suprapubic puncture**

Suprapubic puncture with commercially available catheters such as Cystofix or Lawrence Add-a-Cath catheters is straightforward provided that the bladder is palpable. The skin, fascia and retropubic space are anaesthetised with 0.5 per cent lignocaine. Correct placement is confirmed by aspiration. A large-bore needle is then placed into the bladder, down which a fine catheter is passed (Cystofix) and then secured in position. The other option is to place a plastic suprapubic trocar and cannula, which has a removable plastic strip on the side. A standard 12F Foley catheter can be passed down the cannula, the balloon is inflated, the cannula is extracted and the strip is pulled away from the catheter (Add-a-Cath). If urine cannot be aspirated through the fine-bore needle, passing a suprapubic trocar should not be attempted.

If these devices are not available, a catheter can be placed in the bladder under direct vision through a small incision under local anaesthetic.

**Urethral instrumentation**

In a patient with a known stricture, an experienced urologist may elect to dilate the stricture or to take the patient to theatre to carry out an optical urethroscopy (see Chapter 78).

**Chronic retention**

In chronic retention there is no pain. These patients are at risk of upper tract dilatation because of high intravesical tension – they require urgent urological referral. Men with impaired renal function may develop post-obstructive diuresis following catheterisation. Such men need careful monitoring, with replacement of inappropriate urinary losses by intravenous saline; they are also at risk of haematuria as the distended urinary tract empties. Often it is several days before full renal recovery occurs.

**Retention with overflow**

The patient is incontinent with small amounts of urine passing involuntarily from the distended bladder. It usually follows a neglected retention.

**Indwelling catheters and closed systems of catheter drainage**

The risk of ascending infection is decreased by connecting the catheter to sterile tubing connected to a collecting bag. Irrigations should be avoided unless clot retention occurs. When a catheter has been in situ for a few days, some degree of urethritis and bacteriuria is likely; changing a catheter then entails risks of severe infection if prophylactic antibiotics are not used (Figure 76.13).

**Acute retention due to drugs**

A number of drugs can induce retention, including antihistamines, anti-hypertensives, anti-cholinergics and tricyclic antidepressants.
1314 THE URINARY BLADDER

The acute neuropathic bladder

1 Immediately after spinal cord injury, ’spinal shock’ occurs (see Chapter 35), which may last for days or months. The detrusor is not able to contract, the bladder distends and overflow incontinence occurs. Neglected bladder distension will lead to damage to the detrusor, infection and ultimately renal failure. Management is as follows:

2 The bladder must be emptied by aseptic intermittent catheterisation performed two or three times daily or the use of an indwelling urethral catheter on continuous drainage, making sure that the patient has a high urinary output (3 litres per day) to combat infection. Currently, intermittent catheterisation is preferred as soon as the patient’s spinal injury is stable.

3 Neurological examination must be performed to assess the level of sensory and motor loss. Ischaemic necrosis of the cord may extend below the upper level of cord injury. When sensory loss below the upper level is total, recovery is unlikely. Incomplete lesions may recover somatic and bladder function.

4 Demonstration of intact bulbocavernosus and anal reflexes indicates that the sacral cord and nerves are intact and that reflex bladder contractions are likely to develop, though they may be insufficient to empty the bladder. If there is persistent total loss of reflexes and perineal sensation then either the sacral cord or cauda equina is damaged. In such circumstances, an acontractile bladder is likely. In cauda equina lesions, there may be sensory, motor or mixed loss.

5 Full urodynamic assessment of bladder function should be undertaken when the injury is stable. This allows an accurate assessment of bladder and sphincter activity and will enable decisions to be made about further management; the prime aim is to prevent upper tract damage by promoting good bladder emptying (Summary box 76.5).

The following situations represent the typical patterns of bladder function seen after spinal cord injury.

Lesions above T10

Usually leads to an ‘upper motor neurone’ bladder with reflexes intact but isolated from higher control mechanisms. Such patients are at risk of autonomic dysreflexia. Because of detrusor–sphincter dyssynergia, bladder contractions are high pressure and ineffective in producing bladder emptying; the bladder neck is normally open. If left untreated, upper tract dilatation and renal failure may result. Bladder capacity is usually decreased with the development of trabeculation and a typical ‘fir-tree’ appearance. Patients are incontinent during high-pressure phasic contractions because the sphincter resistance suddenly diminishes.

Some patients with low-pressure bladders that empty may be managed by means of condom drainage. Others will require clean intermittent self-catheterisation (CISC), popularised by Lapides. Patients with poor emptying, low bladder capacity and upper tract dilatation require treatment with endoscopic sphincterotomy and condom drainage. Some carefully selected patients may require bladder reconstruction.

Lesions involving the sympathetic outflow (T11, T12, L1, L2)

These patients are usually similar to the group with lesions above T10.

Damage to the sacral centre S2, S3, S4 and cauda equina lesions

Usually leads to a ‘lower motor neurone’ bladder, also found in spina bifida (myelodysplasia); the detrusor is acontractile. Abdominal straining can produce reasonable emptying but the mainstay is CISC. Some patients may have sensation of filling through the hypogastric nerves, if T11 and T12 are intact. The bladder capacity may be good, but some patients have high resting pressures and high increases during bladder filling, which means that there is a risk to the upper urinary tract. The bladder neck is usually open and the distal sphincter mechanisms may be paralysed but of fixed resistance. Vesicoureteric reflux is common and upper tract damage is frequent in neglected cases. Patients who can achieve satisfactory bladder emptying by means of CISC usually have reasonable continence.

Bladder dysfunction after excision of the rectum or radical hysterectomy

Between 10 and 15 per cent of patients undergoing radical rectal excision for cancer sustain damage to the inferior hypogastric plexus, leading to impotence in the male and neurogenic bladder dysfunction. This type of bladder dysfunction is similar to the cauda equina lesion. Postoperative retention in other patients may also be caused by simple bladder outlet obstruction. The best plan is to catheterise the patient to allow postoperative recovery and then carry out urodynamic investigation to determine the appropriate treatment.

INCONTINENCE OF URINE

Overall, urinary incontinence occurs in 5 per cent of men and 20 per cent of women. Up to 40 per cent of women over the age of 60 years and 50 per cent of institutionalised elderly patients experience regular episodes of urinary incontinence. Health problems include skin breakdown and depression, and loss of esteem and sexual activity. Continence is dependent on normal mobility and brain function allowing a perception of when it is socially acceptable to void, normal bladder sensation, normal voluntary detrusor contraction producing good bladder emptying, a normally competent sphincter mechanism, which relaxes appropriately during a voluntary detrusor contraction allowing good bladder emptying, and good bladder capacity with normally low pressures during filling. This is clearly a fine balance and several factors can cause incontinence. In children, non-neurogenic incontinence is often associated with other dysfunctional conditions such as infections, constipation, psychological factors, increased fluid intake, intentional misconduct or an
overactive bladder. Several investigations are required for diagnosis of urinary incontinence (Summary box 76.6).

**Summary box 76.6**

**Diagnosis of urinary incontinence**

The following investigations are required:
- A careful history and physical examination and completion of frequency voiding charts
- Urodynamic testing in most patients and in all patients in whom surgical intervention is proposed
- Urine culture to exclude infection and measurement of serum creatinine

In selected cases, IVU is carried out if a ureteric fistula is suspected, although ultrasound examination will often provide adequate details.

**Urodynamic testing**

The key to the practical management of lower urinary tract dysfunction, and particularly incontinence, lies with urodynamic investigation. The principle is to artificially simulate bladder filling and emptying while obtaining pressure measurements (Figure 76.14).

The patient attends with a full bladder and is allowed to void in private to measure the maximum urinary flow rate. After voiding, the residual urine is measured by ultrasound. A pair of catheters or a twin-lumen catheter is passed into the bladder, which allows the bladder to be filled at a rate of 50 mL/min while a continuous recording of intravesical pressure is made. To obtain ‘true’ detrusor pressure, a second channel is required to assess intra-abdominal pressure, measured by means of a small intrarectal or intravaginal balloon. The bladder is filled until the patient states that the bladder is full. X-ray screening may be carried out to assess bladder neck closure and urinary leakage during movement or coughing (stress incontinence) or during bouts of phasic detrusor pressure (detrusor instability). The patient is then asked to void at the end of bladder filling after the filling catheter has been removed (Figure 76.15).

The normal bladder will accept approximately 400–550 mL when filled at room temperature at a rate of <50 mL/min. The pressure increase in the bladder should be less than 15 cmH₂O. In addition, phasic pressure increases should not be seen. The normal voiding pressure should not exceed 60 cmH₂O in men and about 40 cmH₂O in women, with a flow rate of between 20 and 25 mL/s.

**Common abnormalities identified during urodynamic testing in incontinence**

**The overactive bladder**

Phasic increases in pressure give rise to urgency and urge incontinence (detrusor overactivity; Figure 76.16). This abnormality is found in patients with neurogenic bladder dysfunction, such as in multiple sclerosis (MS) or Parkinson’s disease or following a stroke or spinal injury, when it is known as detrusor hyperreflexia. About 50 per cent of men with bladder outflow obstruction have detrusor instability, and in about half of them the instability resolves after prostatectomy. Idiopathic detrusor overactivity is common and must be distinguished from genuine stress incontinence (GSI) in women before performing bladder neck suspension procedures. In children, overactive bladder symptoms must be carefully investigated and treated with conservative measures before initiating antimuscarinic therapy.

**Genuine stress incontinence**

This is defined as urinary leakage occurring during increased bladder pressure when this is solely due to increased abdominal pressure and not to increased true detrusor pressure (see Figure 76.15). It is caused by sphincter weakness.

**Chronic urinary retention**

Chronic urinary retention with overflow incontinence is recognised by a large residual volume of urine (Figure 76.17) and is usually associated with high pressures during bladder filling.

![Figure 76.14 Urodynamic study.](image-url)

![Figure 76.15 A section of an ambulatory, natural-fill urodynamic trace.](image-url)
Bladder outflow obstruction
Bladder outflow obstruction is associated with increased voiding pressures, often in excess of 90 cmH\(_2\)O (Figure 76.18), coupled with low urinary flow rates.

Neurogenic dysfunction
Neurogenic bladder dysfunction may also be identified (Summary box 76.7).

Summary box 76.7
Uses of urodynamic testing
- To distinguish GSI (due to sphincter weakness) from detrusor instability in women (see Figure 76.15)
- For the classification of neurogenic bladder dysfunction
- To distinguish bladder outflow obstruction from idiopathic detrusor instability in men
- To investigate incontinence or other lower urinary tract symptoms

Causes of incontinence
There are various ways of classifying the causes of incontinence.

- **Problems of social control.** Patients with dementia often have incontinence because of uninhibited detrusor hyperreflexia and impaired social perception.
- **Storage problems.** Patients with a small bladder capacity owing to fibrosis (tuberculosis, radiotherapy or interstitial cystitis) can develop incontinence. Patients with a small functional capacity owing to severe detrusor instability, neurogenic dysfunction or infection can develop incontinence.
- **Impairment of emptying.** Patients with chronic retention or neurogenic bladder dysfunction have small functional bladder capacities with detrusor overactivity causing incontinence, despite having large residual volumes of urine.
- **Weak sphincter.** This leads to GSI and can follow surgical procedures such as radical prostatectomy in men.
- **Fistulae.** Leakage from fistulae or upper tract duplication with an ectopic ureter.
- **In children,** the causes must be carefully investigated and treated with conservative measures before initiating antimuscarinic therapy.

The common causes may be classified into male, female or mixed-sex groups.

**Male incontinence**
Chronic urinary retention with overflow
This may be due to benign prostatic hypertrophy, carcinoma.

![Figure 76.16](image1)
A section of an ambulatory, natural-fill urodynamic trace. The rectal pressure is in red, the bladder pressure in blue and the subtracted detrusor trace in black. The orange trace is the output of an electronic nappy which records urinary leakage. Phasic activity is shown, which is detrusor instability resulting in urge incontinence.

![Figure 76.17](image2)
An ultrasound scan showing a large post-void residual urine.

![Figure 76.18](image3)
A conventional urodynamic trace showing detrusor pressure during voiding. There has been a change of scale because the pressure was so high; voiding pressures are increased with a low flow rate, which is diagnostic of bladder outflow obstruction.
of the prostate, urethral stricture and, in younger men, hypertrophy of the bladder neck. Examination may reveal that the bladder is distended, and it can be confirmed by ultrasound scanning. The treatment is discussed in Chapter 77.

Post-prostatectomy
Post-prostatectomy incontinence may result from injury to the external sphincter mechanism. Treatment should be conservative initially with pelvic floor exercises, and an anastomotic stricture must be excluded. The condition may necessitate insertion of an artificial urethral sphincter (Figure 76.19).

Female incontinence

Stress incontinence
The most common cause is GSI, although in some parts of the world, vesicourethral fistulae as a result of neglected labour are common. It is usually found in multiparous women with a history of difficult labour. It can be found in normal young women who indulge in competitive trampolining and in patients with epispadias. The classical symptom is urine loss during coughing, laughing, sneezing or a sudden change of posture. The symptoms may change with the menstrual cycle. The volume of urine loss can be measured during an exercise test, which is performed by putting the patient through a standard set of tests with 300 mL of fluid in the bladder; in GSI the fluid losses usually range from 10 to 50 mL. Urinary frequency and urgency are often found in such patients as they try to avoid incontinence by frequent voiding.

Idiopathic detrusor instability can mimic GSI and coexist with it. It is important to make a correct preoperative diagnosis by urodynamic measurements, as the outcome of surgery is suboptimal in women with idiopathic detrusor instability.

Minor to moderate stress urinary incontinence can be controlled by pelvic floor exercises. However, if this fails, surgery is indicated. Standard operations include open colposuspension or the use of a minimally invasive approach involving the insertion of a transvaginal tape (TVT procedure).

Open colposuspension
This operation is carried out through a Pfannenstiel incision with the patient in the Lloyd-Davies position. The vaginal fascia is identified by sweeping the bladder off the vagina and three sutures are placed on each side between the vaginal fascia and the iliopubic ligament. A supra pubic catheter is placed. Voiding difficulties are frequent but usually temporary. It is best to warn women with large bladder capacities and low voiding pressures that this complication may occur and that they may be required to carry out CISC for a period. The operation is very successful for the treatment of GSI, with good results at one year in 90 per cent of patients, which are maintained in about 80 per cent of patients at five years.

Modifications of bladder neck suspension can also be achieved by minimally invasive approaches such as the transvaginal sling. This technique does reduce both the hospital stay and postoperative morbidity.

Incontinence common to both sexes

Idiopathic detrusor overactivity
Phasic increases in bladder pressure may occur during filling in otherwise normal patients (idiopathic) or it may be found in neurogenic bladder dysfunction (when it is known as detrusor hyperreflexia) and bladder outflow obstruction. Idiopathic detrusor overactivity may be symptomless but usually results in symptoms of frequency, urgency, urge incontinence, nocturia or nocturnal incontinence (enuresis) depending on the severity of the instability. It must be distinguished from GSI and from bladder outflow obstruction before surgical treatment. Infection, tuberculosis or carcinoma in situ (CIS) should be excluded. The mainstay of treatment is the use of various anti-cholinergic medications (oxybutynin and tolterodine). Severe symptoms resistant to conventional conservative treatment resulting in major impairment of quality of life may need more aggressive treatment, such as enterocystoplasty or the injection of small doses of botulinum toxin (the toxin from Clostridium botulinum), known as BoTox, which blocks cholinergic neuromuscular transmission, at least for a time.

Ageing
Ageing can result in smooth muscle cell dysfunction, which can cause combinations of small functional capacity, detrusor overactivity, impaired bladder emptying and symptoms of lower urinary tract dysfunction.

Congenital
Congenital causes include ectopic vesicoure and severe epispadias. The abnormal entry of an ectopic ureter distal to the sphincter complex or into the vagina in a female patient should theoretically result in total urinary incontinence. This is discussed in Chapters 6 and 75.

Trauma
Trauma, whether from pelvic surgery or associated with pelvic fracture, may result in disruption of the nerve supply to the bladder or urethra, or in fistula formation.

Infection
Lower urinary tract infection (UTI) may be sufficient to induce urinary incontinence. A history of frequency, burning and a fever should prompt the diagnosis. Symptoms will usually settle with a course of antibiotics, but in the case of recurrent infection further investigation of the urinary tract will clearly be indicated.

Figure 76.19 The artificial urinary sphincter made by American Medical Systems.
Neoplasia
Locally advanced cancers in the pelvis, particularly carcinoma of the cervix in a woman and carcinoma of the prostate in a man, may result in direct invasion of the sphincter mechanism causing incontinence; occasionally, fistula formation may occur in women.

Other causes
Constant dribbling of urine coupled with normal micturition
This occurs when there is a ureteric fistula or an ectopic ureter associated with a duplex system opening into the urethra beyond the urethral sphincter in females or into the vagina. The history is diagnostic, and intravenous pyelography or ultrasound scanning may reveal the upper pole segment, which is often poorly functioning. Treatment is by excision of the aberrant ureter and portion of kidney. A ureteric fistula can be difficult to diagnose and its demonstration may require retrograde ureterography and a high degree of suspicion.

Nocturnal enuresis
This is a condition of young children and young adults. Of course, the time at which children become dry at night varies and, in some, nocturnal enuresis is merely a delayed onset of continence. In others, it persists until late adolescence and is classified into primary and secondary nocturnal enuresis. In children, once neurogenic dysfunction has been excluded, the condition can be associated with other symptoms such as intentional misconduct, infections, constipation and increased fluid intake. These causes must be ruled out before medication is considered.

Primary nocturnal enuresis occurs in patients with nocturnal symptoms alone, which are absent during the day. Often, they have been dry for a period, and the vast majority of patients will eventually become dry. In the meantime, a sympathetic approach to these children is essential. They often respond to a system of rewards using a ‘star’ chart. In addition, the use of DDAVP (a vasopressin analogue) can produce increased urinary concentration at night with a decrease in nocturnal incontinence. Other treatments include the use of an alarm that wakes the child (or at least the child’s parents) when incontinence occurs and medication in the form of an anticholinergic drug such as oxybutynin.

Treatments for incontinence
Treatments are listed below. Management is dependent on making a correct diagnosis.

Management and treatment
Following careful assessment and investigation, many cases of incontinence can improve with simple measures such as lifestyle interventions, pelvic floor exercises with biofeedback, bladder training and incontinence devices where necessary. In mixed urge and stress incontinence, the major component has to be treated first.

Problems of social functioning
Patients with dementia may respond to regular toileting. Anticholinergic agents can cause increased confusion in these patients and often, in severe cases, an indwelling catheter is needed.

Storage problems
Patients with a small bladder capacity because of fibrosis may require augmentation cystoplasty. Detrusor overactivity will require treatment with anti-cholinergic medication but, in severe cases, particularly in neuropathic patients at high risk of upper tract dilatation, bladder substitution (near-total supravaginal cystectomy followed by the need for detubularised ileocoeal segment bladder substitution) or augmentation (enterocystoplasty) may be needed. These procedures should be carried out only after careful assessment in units used to dealing with such problems. Patients with very impaired mobility and MS may require ileal conduit diversion. The use of intravesical injections of BoTox has provided good improvements, and it may avoid or delay the need for major surgery.

Impaired bladder emptying
Patients with overflow incontinence because of bladder outflow obstruction will usually respond well to prostatectomy. Patients with impaired bladder emptying because of neurogenic bladder dysfunction should be treated in the first place by means of CISC.

Weak sphincter
Patients with GSI should be treated by means of pelvic floor exercises initially. Duloxetine can be used as medical treatment for GSI. Bulking agents, such as macroplastique, can be used and can provide good temporary solutions. Surgical treatment by means of colposuspension or TVT may be needed. Those with post-prostatectomy incontinence or neurogenic bladder dysfunction may need to be fitted with an artificial urinary sphincter (Figure 76.19), if they are well motivated and mobile, but careful assessment is required.

Use of appliances
An indwelling catheter drained constantly into a leg urinal may be a satisfactory solution although, in some instances, diversion via an ileal conduit is necessary. In men, a condom urinary appliance may be satisfactory and can avoid an indwelling catheter.

More major surgical treatments
Various types of urinary diversion
Urinary diversion may be required for the treatment of end-stage incontinence that is not otherwise treatable (see later in this chapter).

Bladder substitution procedures
The principle behind these operations is the creation of a low pressure, large-capacity reservoir, which can be made using any segment of bowel isolated on its vascular pedicle (Figures 76.20, 76.21 and 76.22). This is then detubularised by dividing its anti-mesenteric border and suturing this into a plate, which is then reconfigured into a spherical structure. This reservoir can then be anastomosed to the bladder remnant after excision of the fundus above the trigone. If necessary, the ureters can be reimplanted into the bowel segment. This new bladder will need to be emptied by means of CISC in up to 30 per cent of cases.
‘Clam’ enterocystoplasty
This procedure was originally described by Bramble for the treatment of nocturnal enuresis. It has been used in the treatment of idiopathic detrusor instability (Figure 76.23). This procedure can also be used as an augmentation procedure in patients with neurogenic bladder dysfunction and a reasonable bladder capacity (approximately 300 mL).

Fitment of artificial urinary sphincter
See Figure 76.19.

Summary
Treatments for incontinence can be summarised as follows:

1. Conservative measures such as lifestyle interventions, pelvic floor muscle and bladder training.
2. Devices for collection: external penile condom, or an indwelling urethral or suprapubic catheter.
3. Drugs: to decrease the strength of the bladder neck (e.g. adrenergic blockers); with mixed action on the bladder neck and central nervous system (e.g. tricyclic drugs); to inhibit bladder activity (e.g. anti-cholinergic drugs). Botulinum toxin A is used in selected patients. Duloxetine can be used as medical treatment for GSI – it is a serotonin–noradrenaline (norepinephrine) reuptake inhibitor.
5. Increasing outlet: pelvic floor physiotherapy; resistance colposuspension or TVT tapes or slings; periurethral injections of ‘bulking agents’ such as cross-linked collagen or other particles; use of the artificial urinary sphincter.
6. Denervation of bladder: S3 sacral nerve blockade, neurectomy or surgical transection of the bladder to inhibit bladder activity and improve functional capacity. These are rarely used nowadays because of the use of botulinum toxin and the clam cystoplasty or S3 nerve stimulation (see point 7).
7. Sacral nerve stimulation devices can improve incontinence. They involve percutaneous insertion of electrodes through the sacral foramina under radiological control and implantation of an electronic stimulator.

Frank James Bramble, formerly urologist, The Royal Victoria Hospital, Bournemouth, UK.
BLADDER STONES

Definition
A primary bladder stone is one that develops in sterile urine; it often originates in the kidney. A secondary stone occurs in the presence of infection, outflow obstruction, impaired bladder emptying or a foreign body.

Incidence
Until the twentieth century, bladder stone was a prevalent disorder among poor children and adolescents. Because of improved diet, especially an increased protein–carbohydrate ratio, primary vesical calculus is rare.

Composition and cystoscopic appearance
Most vesical calculi are mixed. An oxalate calculus is a primary calculus that grows slowly; usually, it is of moderate size and solitary, and its surface is uneven (Figure 76.24). Although calcium oxalate is white, the stone is usually dark brown or black because of the incorporation of blood pigment. Uric acid calculi are round or oval, smooth and vary in colour from yellow to brown (Figure 76.25). They occur in patients with gout but are also found in patients with ileostomies or with bladder outflow obstruction. A cystine calculus occurs only in the presence of cystinuria and is radio-opaque because of its high sulphur content. A triple phosphate calculus is composed of ammonium, magnesium and calcium phosphates and occurs in urine infected with urea-splitting organisms. It tends to grow rapidly. In some instances it occurs on a nucleus of one of the other types of calculus; more rarely it occurs on a foreign body (Figures 76.26 and 76.27). It is dirty white in colour and of chalky consistency.

A bladder stone is usually free to move in the bladder and it gravitates to the lowest part of the bladder. Less commonly, the stone is wholly or partially in a diverticulum, where it may be hidden from view.

Clinical features
Men are affected eight times more frequently than women. Stones may be asymptomatic and found incidentally.

Symptoms
Frequency is the earliest symptom and there may be a sensation of incomplete bladder emptying. Pain (strangury) is most often found in patients with a spiculated oxalate calculus. It occurs at the end of micturition and is referred to the tip of the penis or to the labia majora; more rarely, it is referred to the perineum or suprapubic region. The pain is worsened by movement. In young boys, screaming and pulling at the penis with the hand at the end of micturition are indicative of bladder stone. Haematuria is characterised by the passage of a few drops of bright-red blood at the end of micturition, and is due to the stone abrading the vascular trigone. Interruption of the urinary stream is due to the stone blocking the internal meatus. Urinary infection is a common presenting symptom.

Figure 76.24 A rough bladder stone.

Figure 76.25 Smooth uric acid-type stones.
Examination
Rectal or vaginal examination is normal; occasionally, a large calculus is palpable in the female. Examination of the urine reveals microscopic haematuria, pus or crystals that are typical of the calculus, for example envelope-like in the case of an oxalate stone or hexagonal plates in the case of cystine calculi. In most patients, the stone is visible on ultrasound or on a plain x-ray (Figure 76.28). Imaging of the whole of the urinary tract should be undertaken to exclude an upper tract stone. Nearly all stones can be dealt with endoscopically. In men with bladder outflow obstruction, endoscopic resection of the prostate should be performed at the same time as the stone is dealt with.

Treatment
The cause of the stone should be sought and treated; this may include bladder outflow obstruction or incomplete bladder emptying in patients with neurogenic bladder dysfunction.

Litholapaxy
The blind lithotrite (Figure 76.29) was an early type of minimally invasive technique. Standard management now includes the optical lithotrite, electrohydraulic lithotrite, Holmium laser or ultrasound probe (Figure 76.30). Other devices include the stone punch, which is useful to crush small fragments further so that they can be evacuated with an Ellik evacuator. Contraindications to perurethral litholapaxy are extremely rare:

• urethral: a urethral stricture that cannot be dilated sufficiently; when a patient is aged below ten years;
• bladder: a contracted bladder;
• stone characteristics: a very large stone.

Ultrasound lithotripsy is extremely safe but appropriate only for small stones. Laser lithotripsy with the holmium laser can deal with most large stones. Once small fragments are produced, the optical lithotrite can be used to finish the job. For evacuation of the fragments, fluid (200 mL) is introduced into the bladder. The evacuator, filled with solution, is fitted on to the sheath. The bulb is compressed slowly and then permitted to expand; the returning solution carries with it fragments of stone.
Percutaneous suprapubic litholapaxy
It is possible to insert a needle into the bladder and then pass a guidewire. As in percutaneous nephrolithotomy, Alken metal dilators can be passed over the guidewire to dilate the track and an Amplatz sheath inserted followed by a large-bore nephroscope. This is the best method to use if it is not possible to carry out litholapaxy per urethram because of a narrow urethra.

Removal of a retained Foley catheter
A retained Foley catheter is usually caused by the channel that connects the balloon to the side arm becoming blocked, usually at the end near the balloon. The best way of dealing with this problem is to further inflate the balloon with 20 mL of water and then burst the balloon percutaneously using a needle under ultrasound screening. If the balloon bursts, it is important to subsequently cystoscope the patient to ensure that any fragments are removed before they can form a foreign body calculus. Cutting off the side arm and attempting to clear the channel with a wire is only occasionally successful.

FOREIGN BODIES IN THE BLADDER
The most common foreign body in the bladder is a fragment of catheter balloon (see above). Occasionally, a foreign body enters through the wall of the bladder, for example non-absorbable sutures used in an extravesical pelvic operation. Complications include:
- lower UTI;
- perforation of the bladder wall;
- bladder stone.

Treatment
A small foreign body can usually be removed per urethram by means of an operating cystoscope. Occasionally, a suprapubic approach using the percutaneous insertion of a cystoscope is needed.

DIVERTICULAE OF THE BLADDER

Definition
The normal intravesical pressure during voiding is about 35–50 cmH₂O; however, pressures as great as 150 cmH₂O may be reached by a hypertrophied bladder endeavouring to force urine past an obstruction. This pressure causes the lining between the inner layer of hypertrophied muscle to protrude, forming multiple saccules. If one or more, but usually one, saccule is forced through the bladder wall, it becomes a diverticulum (Figure 76.31). Congenital diverticula are the result of a developmental defect.

Aetiology of diverticulae
Congenital diverticula
These are situated in the midline anterosuperiorly and represent the unobliterated vesical end of the urachus.

Pulsion diverticula
The usual cause is bladder outflow obstruction.

Pathology
The mouth of the diverticulum is situated above and to the outer side of one ureteric orifice. Exceptionally, it is near the midline behind the interureteric ridge. The size varies from 2 to 5 cm, but they may be larger. Diverticula are lined by bladder mucosa and the wall is composed of fibrous tissue only (compare with a traction diverticulum). A large diverticulum enlarges in a downward direction and sometimes may obstruct a ureter – probably because of peridiverticular inflammation.

Complications
Recurrent urinary infection
As the pouch cannot empty itself efficiently, there remains a stagnant pool of urine within it. Peridiverticulitis can cause dense adhesions between the diverticulum and surrounding structures. Squamous cell metaplasia and leukoplakia are infrequent complications.

Bladder stone
This develops as a result of stagnation and infection. The stone often protrudes into the bladder.
**Hydronephrosis and hydroureter**
This is extremely rare and is a consequence of peridiverticular inflammation and fibrosis.

**Neoplasm**
Neoplasm arising in a diverticulum is an uncommon complication (<5 per cent). The prognosis is dependent on the stage of the tumour (see below).

**Clinical features**
An uninfected diverticulum of the bladder usually causes no symptoms. The patient is nearly always male (95 per cent) and over 50 years of age. Symptoms are those of associated urinary tract obstruction, recurrent infection and pyelonephritis. Haematuria (due to infection, stone or tumour) is a symptom in about 30 per cent. In a few patients micturition occurs twice in rapid succession (the second act may follow a change of posture).

**Diagnosis**
Diverticula are usually discovered incidentally on cystoscopy or ultrasound (Figures 76.32, 76.33 and 76.34).

**Indications for operation**
Operation is necessary only for the treatment of complications. Provided the diverticulum is small and associated outflow obstruction has been dealt with by prostate resection, there is no reason to resect the diverticulum. Even a large diverticulum may not require treatment in the absence of infection or other complications.

**Combined intravesical and extravesical diverticulectomy**
A ureteric stent is passed up the ureter on the affected side and the anterior bladder wall is exposed through a suprapubic incision. The bladder is incised in the midline and the diverticulum is packed with a strip of gauze. The neck of the diverticulum is separated from the ureter and, when the pouch is free, it is severed from the bladder. The resulting defect is closed in a single layer with 2/0 absorbable sutures. A suprapubic catheter is left in place and an extravesical drain is inserted. An alternative method, if the sac is densely adherent, is to carry the incision in the bladder down to the rim of the diverticular orifice, then to detach the diverticulum together with its fibrous rim. The incision in the bladder is closed and the diverticulum left in position with a corrugated drain placed into it for 2–3 days. The track fibroses rapidly after removal of the drain. If bladder outlet obstruction is present, prostatectomy should be carried out at the same time as the diverticulectomy, using any appropriate method (transurethral resection of the prostate (TURP), laser or open) (Summary box 76.8).

**Figure 76.33** Occasional appearance of a diverticulum with inadequate distension of the bladder.

**Figure 76.34** Bladder diverticulum demonstrated by ultrasound.
Traction diverticulum (synonym: hernia of the bladder)

A portion of the bladder protruding through the inguinal or femoral hernial orifice occurs in 1.5 per cent of such herniae treated by operation (Figure 76.35).

**URINARY FISTULAE**

**Congenital urinary fistulae**

The causes of congenital urinary fistulae include:

- ectopia vesicae;
- a patent urachus – the presence of a urinary leak from the umbilicus, present at birth or commencing soon after, suggests this diagnosis. In adult life, infection in a urachal cyst may produce a fistula and adenocarcinoma may occur (Figures 76.36 and 76.37). Treatment is by means of excision of the urachal tract and closure of the bladder once distal obstruction has been excluded;
- in association with imperforate anus (see Chapters 8 and 73).

**Traumatic urinary fistulae**

Perforating wounds, damage not recognised during surgery or poor healing and avascular necrosis following radiotherapy and surgery may lead to fistula formation. Also, clot retention occurring after an open bladder operation may lead to dehiscence of the wound and a fistula, which will heal quickly provided the bladder is kept empty with an indwelling catheter.

**Vesicovaginal fistulae**

**Aetiology**

- Obstetric. The usual cause is protracted or neglected labour.
- Gynaecological. The operations chiefly causing this complication are total hysterectomy and anterior colporrhaphy.
- Radiotherapy.
- Direct neoplastic infiltration. Exceptionally, carcinoma of the cervix ulcerates through the anterior fornix to implicate the bladder.

When an injury to the bladder is recognised and repaired, leakage is uncommon, but escape of urine will quickly follow if such damage passes unnoticed. However, most vesicovaginal fistulae are the result of ischaemic necrosis of the bladder because of prolonged pressure of the fetal head in obstetric cases. In gynaecological cases, the ischaemia is brought about by grasping the bladder wall in an artery forceps, including the bladder wall in a suture or perhaps even by local oedema or haematoma. Leakage because of necrosis of tissue seldom manifests itself before 7 days after the operation. An intractable fistula following radiotherapy for carcinoma of the cervix uteri may arise from avascular necrosis years after the apparent cure of the original lesion.
Clinical features
There is leakage of urine from the vagina and excoriation of the vulva. Vaginal examination may reveal a localised thickening on its anterior wall or in the vault. On inserting a vaginal speculum, urine will be seen escaping from an opening in the anterior vaginal wall.

The ‘three-swab test’
The differential diagnosis between a ureterovaginal and vesicovaginal fistula can be made by placing a swab in the vagina and injecting a solution of methylene blue through the urethra; the vaginal swab becomes coloured blue if a vesicovaginal fistula is present. Cystoscopy and bilateral retrograde ureterography provide a more reliable demonstration. An IVU should be performed to exclude a coincidental ureterovaginal fistula (ureterovaginal fistula occurs with vesicovaginal fistula in about 10 per cent of cases). Usually, the IVU shows some upper tract dilatation resulting from partial obstruction.

Treatment
Just occasionally, conservative management of a vesicovaginal fistula following hysterectomy, by urethral bladder drainage, is successful; however, the majority of fistulae will require definitive surgical repair. A low fistula (supravaginal) is best repaired per vaginam. The fistula is exposed, the bladder is closed using absorbable sutures and the vagina subsequently closed with a separate layer. A urethral catheter should be left in situ for at least 10 days. For higher (supratrigonal) fistulae, a transvaginal approach can be difficult. These patients should always be cystoscoped before the repair procedure and bilateral ureterograms performed. For high fistulae, a suprapubic approach is the best method in most hands; however, some experts will aim to carry out vaginal closure in most cases that have not involved complex surgery or radiotherapy.

To repair a ureterovaginal fistula, an extraperitoneal approach to the ureter via the previous Pfannenstiel incision is made. Considerable adhesions will be encountered, but the ureter can usually be found above the level of the injury and followed down. Reimplantation into the bladder is often required. Depending on the amount of ureter lost, it may be possible to achieve reimplantation with a psoas hitch procedure. If the gap is too large, a Boari flap of anterior bladder wall should be cut and brought over to meet the ureter and a reimplant performed. The most important principle of ureteric reimplantation is that there should be no tension on the repair.

Fistulae from renal pelvis to skin or gut
Tuberculosis of a kidney may result in a fistula to the duodenum, colon or skin. Similarly, a pyonephrosis may discharge into the gut or onto the skin. Duodenal ulcer involving the pelvis of the right kidney, Crohn’s disease involving the renal pelvis or ureter, or cases of xanthogranulomatous pyelonephritis may cause fistulae. A longstanding urinoma will occasionally fistulate into the gut.

Fistulae arising from infection
The most common cause is diverticulitis of the colon. Fistulae may also follow Crohn’s disease, appendical abscess or pelvic sepsis after acute salpingitis, or pelvic surgery.

The onset of a fistula from diverticular disease may well be treated as a simple urinary infection. The diagnosis can be difficult to make, but on cystoscopy a patch of oedema on the left side of the vault is suggestive and bubbles of gas may be seen (Figure 76.38). A cystogram may reveal the fistula. The passage of gas per urethram in a patient is most suggestive (provided that diabetes resulting in urinary infection with a gas-forming organism is excluded).

Treatment of fistulae caused by diverticular disease
In most patients a single-stage operation is indicated provided that the surgeon is experienced in colonic surgery. At laparotomy, the communication is separated, the hole in the bladder being closed and patched with omentum, and the segment of diseased bowel resected; it is most important to ensure that the left colon and, if necessary, the splenic flexure are fully mobilised to facilitate a tension-free, well-vascularised anastomosis. The bladder is drained by a urethral catheter.

Fistulae caused by carcinoma
By the time that a fistula between the bowel and the bladder has developed, the tumour is usually locally advanced but may be operable.

Urethral fistulae in the male
These occur as the result of infection above a stricture producing a paraurethral abscess that ruptures into the urethra, allowing extravasation to occur suddenly into the scrotum and perineum. Urine and infection extend into the upper 2.5 cm of the thigh and lower abdominal wall. Widespread cellulitis and tissue necrosis (which may lead to Fournier’s gangrene) may occur unless drainage of urine is achieved by suprapubic cystotomy and the tissue planes are freely drained by inguinal and scrotal incisions.

Neoplastic fistulae
Primary bladder tumours very rarely produce fistulae. Involvement of the bladder by tumours of the cervix, uterus, colon and rectum can produce fistulae, as may sarcoma of the small gut. Carcinoma of the prostate rarely produces a rectal fistula. Treatment is difficult and in most cases only palliative...
relief can be given. It is rarely in the patient’s interest to carry out urinary diversion, although minimally invasive techniques, such as placement of ureteric stents, can be helpful in palliating symptoms (Summary box 76.9).

**Summary box 76.9**

**Fistulae**
- A fistula is a communication between two epithelium-lined surfaces.
- Most urinary fistulae are vesicovaginal and result from obstetric trauma; an associated ureterovaginal fistula occurs in about 10 per cent of cases.
- A ‘three-swab test’ is used to aid the diagnosis. An examination under anaesthesia, vaginoscopy, and cystoscopy and IVU should be performed and, if necessary, retrograde ureterography.
- Conservative management is rarely successful.
- The principles of repair include good exposure, excision of diseased tissue and tension-free vascularised repair in anatomic layers.
- Fistulae caused by radiation, cancer and sepsis can be complex with multiple tracts.
- The persistence of a fistula on the skin implies the presence of distal obstruction, chronic infection, such as tuberculosis, or a foreign body, such as a stone or non-absorbable ligature.

**LOWER URINARY TRACT INFECTION AND CYSTITIS**

Infection of the bladder gives rise to symptoms of frequency, urgency, suprapubic discomfort, dysuria and cloudy offensive urine. These symptoms are often known as ‘cystitis’. Lower UTIs are much more common in women than in men, particularly in the under 50s. It should be remembered that a lower UTI is often associated with upper tract colonisation and the presence of associated loin pain, pyrexia, rigors and malaise (these symptoms represent complicated infection and should be taken seriously as serious sepsis can ensue).

**Isolated infection**

A single episode of lower tract infection occurs frequently in females and is rarely complicated.

**Recurrent infection**

Recurrent infection may be associated with an underlying predisposing cause or may be a result of bacterial resistance. In healthy women, infection after intercourse can occur without any demonstrable abnormality of the urinary tract. Repeated attacks of UTI in women, or a single attack in a man or a child of either sex, should always be followed by investigation to discover and treat the cause; sometimes, however, no cause can be found. Asymptomatic bacteriuria is common and investigation may fail to demonstrate any underlying cause.

**Infection in males**

Although more common in female adults, the incidence of infection is higher in male infants as underlying urinary tract abnormalities are more frequent. Complicated or recurrent infection in adult males warrants prompt antibiotic therapy and investigation to exclude an underlying cause.

**Infection in pregnancy**

The incidence of asymptomatic bacteriuria in pregnant women is twice as high as in non-pregnant women. Simple uncomplicated infection can be treated following urine culture with an appropriate antibiotic that is not contraindicated in pregnancy, such as cephalosporin or ampicillin. Non-responsive infection may require intravenous therapy and an ultrasound scan.

**Predisposing causes of urinary tract infection**

- Incomplete emptying of the bladder, secondary to bladder outflow obstruction, a bladder diverticulum, neurogenic bladder dysfunction or decomposition of the detrusor muscle.
- A calculus, foreign body or neoplasm.
- Incomplete emptying of the upper tract, dilatation of the ureters associated with pregnancy, or vesicoureteric reflux. In childhood, the mainstay of treatment of vesicoureteric reflux is antibiotic therapy; operation is reserved for those with recurrent infection despite antibiotics or with severe upper tract dilatation.
- Oestrogen deficiency, which may give rise to lowered local resistance.
- Colonisation of the perineal skin by strains of *Escherichia coli* expressing molecules that facilitate adherence to mucosa.
- Diabetes.
- Immunosuppression.

**Avenues of infection**

Ascending infection from the urethra is the most common route (see Chapter 74). The organisms originate in the bowel, contaminate the vulva and reach the bladder. The passage of urethral instruments may cause infection in either sex, especially when the bladder contains residual urine (Figure 76.39). Other routes are less common and include descending infection from the kidney (tuberculosis), haematogenous spread, lymphogenous spread and spread from adjoining structures (Fallopian tube, vagina or gut).

**Bacteriology**

Bacterial virulence factors affect the ability of a pathogen to infect the host. The possession of pili (rod-shaped structures) that project from the outer membrane increases adhesiveness. The type of pilus can be used to classify the pathogen involved. *Escherichia coli* is the most common organism followed by *Proteus mirabilis*, *Staphylococcus epidermidis* and *Streptococcus faecalis*. Infection with other organisms or infection with mixed organisms is found in patients with neurogenic bladder dysfunction or those with a longstanding indwelling urethral catheter. These organisms include *Pseudomonas*, *Klebsiella*, *Staphylococcus aureus* and various streptococci. Tuberculous infection is considered below.

The presence of pus cells without organisms calls for examination for *Mycobacterium tuberculosis* and *Neisseria gonorrhoeae*. Having eliminated these possibilities, the underlying condition may be abacterial cystitis, carcinoma in situ, renal papillary necrosis, stones or incomplete treatment of a urinary infection.
Clinical features
These include frequency, pain, haematuria and pyuria. Pyrexia and rigors are not associated with a simple UTI, but are a sign of upper tract infection or septicaemia.

Examination
On examination, there is tenderness over the bladder. Initial and midstream urine specimens should be collected in a male as acute prostatitis may be present (see below), which will lead to threads in the initial specimen. The midstream specimen must be subjected to microscopy and culture, and the sensitivity of any organisms assessed.

Treatment
Treatment should be commenced immediately and modified if necessary when the bacteriological report is to hand. The patient is urged to drink. Appropriate first-line antibiotics depend on local likely sensitivities, but would include trimethoprim or one of the quinolones. Failure to respond indicates the need for further investigation to exclude predisposing factors. It is important to check for associated allergies or other drugs or conditions that might preclude the use of some antibiotics (e.g. concomitant administration of methotrexate and trimethoprim (both inhibit tetrahydrofolate reductase)).

Investigation
Investigation may be needed in the male or when recurrent infection occurs. This includes measurement of urinary flow rates and post-void residual urine. IVU, ultrasound scan or CT scanning will usually be carried out together with cystoscopy.

Summary box 76.10

UTI in adults
- Isolated UTI in adults is not infrequent and is more common in women
- Recurrent or complicated infection (haematuria, rigors) warrants appropriate antimicrobial therapy and investigation
- Investigation to exclude a predisposing cause includes urinalysis, microscopy and culture, upper tract imaging and cystoscopy
- Mycobacterium tuberculosis, Neisseria gonorrhoeae or Mycoplasma genitalium should be suspected if pus cells are present but urine culture is negative
- Cancer, especially CIS, masquerading as infection may be diagnosed as abacterial cystitis

Difficult cases may require urodynamic investigation (Summary box 76.10).

SPECIAL FORMS OF LOWER URINARY TRACT INFECTION

Acute abacterial cystitis (acute haemorrhagic cystitis)
The patient presents with severe UTI. Pus is present in the urine but no organism can be cultured. It is commonly sexually acquired, but tuberculous infection and CIS must be ruled out. The underlying causative organism may be Mycoplasma or herpes simplex virus. Cyclophosphamide can also cause this problem.

Frequency–dysuria syndrome (urethral syndrome)
This consists of symptoms of lower tract infection but with negative urine cultures. CIS, tuberculosis and interstitial cystitis should be excluded. Most urologists advise patients to adopt general measures such as wearing cotton underwear, using simple soaps, adopting general perineal hygiene measures and voiding after intercourse. Other treatments include cystoscopy and urethral dilatation, although the benefits remain doubtful.

Tuberculous urinary infection
Tuberculous urinary infection is secondary to renal tuberculosis. Early tuberculosis of the bladder commences around the ureteric orifice or trigone, the earliest evidence being pallor of the mucosa due to submucous oedema. Subsequently, tubercles may be seen and, in longstanding cases, there is marked fibrosis and the capacity of the bladder is greatly reduced (Figure 76.40).

Treatment
Tuberculous infection usually responds rapidly to antituberculous drugs but occasionally the involved kidney and ureter have to be removed. If the bladder remains of low capacity, patients will have severe symptoms and the upper tracts are at risk because of high filling pressures and vesicoureteric reflux. Such

Albert Ludwig Siegmund Neisser, 1855–1916, Director of the Dermatological Institute, Breslau, Germany (now Wroclaw, Poland).
patients, after appropriate chemotherapy, respond well to bladder augmentation. The ureters may need reimplantation.

Bladder augmentation by ileocystoplasty or caecocystoplasty
The fibrosed supratrigonal bladder is removed and the bladder augmented with a segment of bowel. This may consist of intact caecum, a detubularised segment of ileum or a detubularised ileocaecal segment (see Figures 76.20, 76.21 and 76.22).

Interstitial cystitis (Hunner’s ulcer)
For practical purposes, this is confined to women. The first symptom is increased frequency; pain, relieved by micturition and aggravated by jarring and overdistension of the bladder, is another characteristic symptom. In most patients, pyuria and urinary infection are absent. Haematuria also occurs. The aetiology remains as obscure as it was when Guy Hunner described the condition in 1914. It consists of a chronic pan-cystitis, often with marked infiltration with lymphocytes and macrophages. Fibrosis of the vesical musculature and areas of avascular atrophy of the epithelium occur. Ulcration of the mucosa occurs in the fundus of the bladder. In severe cases, the bladder capacity is reduced to 30–60 mL. The characteristic linear bleeding ulcer is caused by splitting of the mucosa when the bladder is distended under anaesthesia. Inflammation of all coats of the bladder is present with granulation tissue in the submucosa underlying the ulcer. The muscularis is hypertrophied and the peritoneum in proximity to the area of maximum disease is thickened. The inflammation may involve the trigone, the urethra and, in severe cases, the peritoneum. Pronounced mast cell infiltration is seen but is not specific. It is important to check urinary cytology and to biopsy the mucosa to exclude underlying neoplastic disease.

On cystoscopy, the characteristic ulcer is found in the fundus, but it may be absent. This area bleeds readily as the bladder is decompressed. Treatment is difficult and unsatisfactory. Hydrostatic dilatation under anaesthesia may give relief for some months. Instillation of dimethylsulphoxide results in improvement in some patients. Other drugs that have been tried include intravesical heparin, oral ranitidine and steroid therapy. Patients with severe symptoms may well require cystectomy and orthotopic bladder substitution. In patients with severe inflammation involving the trigone and urethra, this operation may not result in complete relief and some type of urinary diversion may be needed.

Alkaline encrusting cystitis
Alkaline encrusting cystitis is rare and is due to urea-splitting organisms causing phosphatic encrustations on the bladder mucosa of elderly women. There are symptoms of chronic UTI and a plain x-ray shows the bladder outline. The encrustations may be removed by bladder irrigation and the infection treated with appropriate antibiotics.

Cystitis cystica
Under the influence of chronic inflammation, the surface epithelium sends down buds, resulting in minute cysts filled with clear fluid, most abundant on the trigone. This is frequently found in patients with recurrent frequency and dysuria.

SCHISTOSOMIASIS OF THE BLADDER

Geographical distribution
The disease is endemic in Egypt, parts of Africa, Israel, Syria, Saudi Arabia, Iran, Iraq and the shores of China’s great lakes. Dwellers of the Nile valley have suffered for centuries. Marshes or slow-running fresh water provide the habitat for the freshwater snail (Bulinus truncatus) that is the intermediate host (see Chapter 6).

Mode of infestation
The disease is acquired through exposure of the skin to infected water, which usually occurs while bathing. The free-swimming, bifid-tailed embryos ( cercariae) of the trematode Schistosoma haematobium penetrate the skin. Shedding their tails, they enter blood vessels and are swept to all parts of the body but they flourish in the liver where they live on erythrocytes and develop into male and female worms. Sexual maturity having been attained, the nematodes leave the liver and enter the portal vein. The male worm bends into the shape of a gutter (the gynaecophoric canal) into which a female worm nestles, and the pair makes its way towards the inferior mesenteric vein. Schistosoma haematobium has an affinity for the vesical venous plexus, which it reaches through the portosystemic anastomotic channels.

Having reached the bladder, the female worm eventually enters a submucous venule which is so small that it completely blocks it. It now proceeds to lay about 20 ova in a chain; each ovum is provided with a terminal spine that penetrates the vessel wall. A heavily infected subject passes hundreds of ova a day. If the ova reach fresh water, the low osmotic pressure causes rupture and the ciliated miracidium emerges. To survive, it must reach and penetrate the intermediate snail host within 36 hours. Within the snail’s liver, the miracidium enlarges and gives rise...
to myriads of daughter cysts, which are set free on the death of the snail. A single miracidium begets thousands of cercariae to complete the life cycle.

**Clinical features**

After penetration of the skin, urticaria lasting about 5 days can occur (swimmer’s itch). Following an incubation period of 4–12 weeks, a high evening temperature, sweating and asthma, together with leukocytosis and eosinophilia, occur. Usually, an asymptomatic period of several months supervenes before the ova are released, causing the typical early sign and symptom of intermittent, painless, terminal haematuria. Men are affected three times more frequently than women.

**Examination of the urine**

The last few millilitres of an early-morning urine specimen are collected and centrifuged. Examination on several consecutive days may be required, but a negative result does not exclude bilharziasis, especially in patients no longer resident in bilharzial districts. Antibody detection by enzyme-linked immunosorbent assay (ELISA) using *Schistosoma mansoni* adult microsomal antigen (MAMA) can be performed. The test is positive one month after infection and is specific for *Schistosoma mansoni* and *Schistosoma haematobium*.

**Cystoscopy**

Depending on the length of time for which the disease has remained untreated, cystoscopy will reveal one or more of the following:

1. **Bilharzial pseudotubercles** are the earliest specific appearance of the disease (Figure 76.41);
2. **Bilharzial nodules** (Figure 72.42) are caused by the fusion of tubercles;
3. **‘Sandy patches’** are the result of calcified dead ova with degeneration of the overlying epithelium (Figure 76.43);
4. **Ulceration** is the result of sloughing of the mucous membrane containing dead ova (Figure 76.44);
5. **Fibrosis** is mainly the result of secondary infection;
6. **Granulomas**. Bilharzial masses are caused by the aggregation of nodules;
7. **Papillomas** are more pedunculated (Figure 76.45);
8. **Carcinoma** is a common end result in grossly infected bilharziasis of the bladder that has been neglected for years.

**Treatment**

Safe and effective drugs are available for the treatment of schistosomiasis, including praziquantel taken in three doses of 20 mg/kg (total 60 mg/kg) 4 hours apart. It takes many months for dead ova to be expelled and, even after repeated courses and healing of the bladder lesion, living bilharzial worms have been found at necropsy in the portal system.

Other complications, requiring specific treatment, include the following:

- urinairy calculi;
- stricture of the ureters;
- prostatoseminal vesiculitis;
- fibrosis of the bladder and bladder neck (Figure 76.46);
- bilharzial urethral strictures;
- squamous bladder cancer.

**NEOPLASMS OF THE BLADDER**

In total, 95 per cent of primary bladder tumours originate in transitional epithelium; the remainder arise from connective tissue (angioma, myoma, fibroma and sarcoma) or are extra-adrenal phaeochromocytomas.
Secondary tumours of the bladder are common and most frequently arise from the sigmoid and rectum, the prostate, the uterus or the ovaries, although bronchial neoplasms may also spread to the bladder.

Pathology

**Benign papillary tumours**
The papilloma consists of a single frond with a central vascular core with villi; it looks like a red sea anemone (Figures 76.47 and 76.48). Inverted papilloma is a condition in which the proliferative cells penetrate under normal mucosa so that the lesion is covered with smooth urothelium. It is benign.

**CARCINOMA OF THE BLADDER**

Histological types of bladder cancer include urothelial, squamous and adenocarcinoma (or mixed, as a result of metaplasia in a transitional cell carcinoma (TCC)). Over 90 per cent are urothelial in origin. Pure squamous carcinoma is uncommon (approximately 5 per cent), except in areas where bilharzia is endemic. Primary adenocarcinoma, which arises either from the urachal remnant or from areas of glandular metaplasia, accounts for 1–2 per cent of cases.

**Urothelial cell carcinoma**

**Aetiology**
Cigarette smoking is the main aetiological factor (40 per cent of cancers). Occupational exposure to urothelial carcinogens remains common. The first suspicion of a chemical cause for bladder cancer was raised by Rehn in 1895 when he recorded a series of tumours in workers in aniline dye factories. Hueper showed that 2-naphthylamine was carcinogenic in dogs. Subsequent investigation demonstrated that the following compounds may be carcinogenic:

- 2-naphthylamine;
- 4-aminobiphenyl;
- benzidine;
- chloronaphazine;
- 4-chloro-o-toluidine;
- o-toluidine;
- 4,4'-methylene bis(2-chloroaniline);
- methylene dianiline;
- benzidine-derived azo dyes.

Occupations associated with an increased risk of bladder cancer are:

- textile workers;
- dye workers;
- tyre rubber and cable workers;
- petrol workers;
- leather workers;
- shoe manufacturers and cleaners;
- painters;
- hairdressers;
- lorry drivers;
- drill press operators;
- chemical workers;
- rodent exterminators and sewage workers.

Ludwig Rehn, 1849–1930, surgeon, Frankfurt am Main, Germany.
Bladder cancer became a prescribed industrial disease (No. 39) in 1953, and previously exposed workers may be entitled to compensation. Balkan nephropathy is associated with an increased incidence of upper tract urothelial tumours (see Chapter 75).

A series of genetic events has been clearly implicated in cancer formation but is outside the remit of this chapter. Activation of dominantly acting oncogenes such as ras and c-erbB-1 and -2, and transcription factors such as E2F3, have been reported in bladder cancer, as has the inactivation of tumour-suppressor genes such as p53, p21, p16 and the retinoblastoma gene. Activation of many other genes occurs including those coding for enzymes that dissolve the basement membrane, such as the metalloproteinases (stromelysin, collagenases and elastase), lysosomal enzymes such as the cathepsins and others including urinary plasminogen activators; angiogenic factors (e.g. vascular endothelial growth factor (VEGF)) and other peptide growth factors such as the epidermal growth factor and its receptor (EGFR) also have a role to play, as well as the fibroblast growth factor and its receptor-3 (FGFR-3) which was found to be altered mostly in non-muscle invasive disease. These changes are common to several tumour types, including prostate cancer (Summary box 76.11). More recently, new approaches through genome-wide association studies allowed the investigation of genetic susceptibility for urothelial cancer. Several new loci were identified, but to date, only two, NAT2 (N-acetyltransferase 2) and GSTM1 (glutathione S-transferase Mu 1) have been demonstrated to be consistent germline susceptibility markers. These genetic markers do not yet have sufficient discriminatory ability to be used for clinical decision making.

**Tumour staging and grading**

Study of the biological behaviour of transitional cell cancer of the bladder shows that cancers fall into the three following groups. Depth of invasion (T) from the tumour–node–metastasis (TNM) classification and grade (World Health Organization I, II or III) are important factors in planning treatment and determining prognosis in bladder cancer.

- **Non-muscle-invasive** pTa (Figure 76.48) and pT1 tumours account for 70 per cent of all new cases; the previous terminology of ‘superficial’ bladder cancer in this category has now been abandoned; it is important to distinguish however ‘low-risk’ urothelial cancers which are unlikely to progress, such as well differentiated (G1) pTa tumours (not invading lamina propria), from ‘high-risk’ cancers such as poorly differentiated (G3) pT1 cancers (invading lamina propria), which should be followed up carefully and treated aggressively as necessary. This can be determined by careful histological examination. Single papillary pTa tumours account for a significant proportion of bladder cancers and carry an excellent prognosis.

- **Muscle-invasive disease** (pT2) accounts for 25 per cent of new cases. Such tumours carry a much worse prognosis as they are subject to local invasion and distant metastasis.

- **Flat, non-invasive** CIS (primary CIS) accounts for 5 per cent of new cases. Unless diagnosed and treated promptly, it carries a poor prognosis (Summary box 76.12). The highest risk non-muscle invasive cancer is found with multifocal poorly differentiated tumours invading lamina propria (pT1G3) in the presence of CIS.
Non-muscle invasive bladder cancer

These are usually papillary tumours that grow in an exophytic fashion into the bladder lumen (Figures 76.47 and 76.48). They may be single or multiple and may appear pedunculated, arising on a stalk with a narrow base, but if the tumours are less well differentiated they are more solid with a wider base. The mucosa around the tumour is often rather oedematous, with angio- looking, dilated blood vessels. These areas may contain in situ changes (concomitant CIS).

The urothelium elsewhere in the bladder may appear rather oedematous and velvety; this suggests a generalised ‘field change’ with the presence of widespread CIS. The most common sites for superficial tumours are the trigone and lateral walls of the bladder.

After initial complete treatment by endoscopic transurethral resection (TURT), patients with pTa or pT1 disease may develop two problems:

1. About 50–70 per cent develop recurrent tumours that may be single or multiple, and the recurrences may occur on one or on many occasions. The recurrent tumours are usually of the same stage or grade as the primary tumour. High-grade, multiple tumours with concomitant CIS are most likely to develop recurrent disease.

2. About 15 per cent will develop a recurrent tumour that invades the bladder muscle. The risk of such progression increases with high-grade disease, pT1 disease, multiple primary disease and concomitant CIS. Many urologists now regard the presence of pT1 grade 3 tumours as an indication for offering the patient immediate cystectomy because of the excellent outcome.

This behaviour provides the rationale for performing check cystoscopies. The factors that result in an increased recurrence and progression rate are:

- high grade;
- pT1 disease;
- concomitant CIS;
- multiple primary tumours;
- recurrent disease at the first check cystoscopy three months after diagnosis.

Patients presenting with a solitary grade 1 or grade 2 pTa tumour without concomitant CIS, which does not recur within the first six months, have an excellent outcome. Patients with recurrent low-grade disease can be treated with intravesical instillations of a chemotherapeutic agent such as mitomycin-C or epirubicin with regular cystoscopic checkups and repeat biopsies, or immunotherapy using regular intravesical instillations of Bacille Calmette–Guérin (BCG), an attenuated form of the anti-tuberculosis vaccine. Patients with high-grade pTa or pT1 disease are at high risk and should be counselled very carefully. The options include immediate cystectomy or a more conservative approach with a course of BCG followed by careful cystoscopic assessment and maintenance instillations. Assessment. The presence of persistent disease after BCG therapy is reason to offer cystectomy (Summary box 76.13).

Muscle-invasive bladder cancer

Muscle-invasive tumours are nearly always solid (Figure 76.49), although there may be a low tufted surface. These tumours are often large and broad based, having an irregular, ulcerated, appearance within the bladder. The incidence of metastases, whether from lymphatic invasion in the pelvis or blood-borne to the lung, liver or bones, is much more common and will cause the death of 30–50 per cent of patients (Summary box 76.14).
In situ carcinoma

The histological appearance of irregularly arranged cells with large nuclei and a high mitotic index replacing the normally well-ordered urothelium is known as CIS. It may occur alone (primary CIS) or in association with a new tumour (concomitant CIS) or it may occur later in a patient who has previously had a tumour (secondary CIS). It can only be diagnosed when a biopsy is examined under the microscope. It may cause severe symptoms of dysuria, suprapubic pain and frequency (hence its old name of malignant cystitis). It carries a risk for the patient of developing a malignant muscle-invasive cancer. Without treatment, 50 per cent will die of invasive bladder cancer. It can be treated initially with intravesical BCG, but failure of response is an indication for cystectomy. CIS cannot be treated with external beam radiotherapy.

Pure squamous cell carcinoma of the bladder

Squamous cell tumours tend to be solid and are nearly always associated with muscle invasion. This is the most prevalent form of bladder cancer in areas where bilharzia is endemic. Squamous cell tumours may be associated with chronic irritation caused by stone disease in the bladder as a result of metaplasia.

Pure adenocarcinoma

Adenocarcinoma accounts for approximately 1–2 per cent of all bladder cancers. It usually arises in the fundus of the bladder at the site of the urachal remnant. Occasionally, primary adenocarcinomas arise at other sites and probably originate from areas of glandular metaplasia. Such tumours need to be distinguished from secondary cancer, and can be treated with partial cystectomy.

CLINICAL FEATURES OF BLADDER CARCINOMA

Painless gross haematuria is the most common symptom and is indicative of a bladder carcinoma until proven otherwise. Often, however, the patient fails to declare the symptom to their GP. The bleeding may give rise to clot formation and clot urinary retention.

Constant pain in the pelvis usually heralds extravesical spread. There is often frequency and discomfort associated with urination. Pain in the loin or pyelonephritis may indicate ureteric obstruction and hydronephrosis. A late manifestation is nerve involvement causing pain that is referred to the suprapubic region, groins, perineum, anus and into the thighs.

It is also important to assess the patient as a whole. Many are elderly men who have been lifelong smokers and who suffer from chronic obstructive airway disease or cardiovascular disease. Their suitability for major surgery must be borne in mind.

INVESTIGATION OF BLADDER CARCINOMA

Urine

Urine should be cultured and examined cytologically for malignant cells. This is not a good screening test but a positive result is highly specific, and it is mostly helpful with high grade disease and CIS. New tests are being developed based on the presence of antigens such as nuclear matrix proteins (NMP22) or mini-chromosome maintenance (MCM) proteins, which may be able to detect new or recurrent tumours; and epigenetic events such as methylated panels of markers or microRNA fragments. These tests continue to be under evaluation and are not used routinely.

Blood

Estimation of haemoglobin and the level of serum electrolytes and urea should be carried out.

CT, magnetic resonance, IVU or ultrasound scanning

This should be performed on all patients with painless haematuria. Occasionally, the preliminary film shows a faint shadow of an encrusted neoplasm of the bladder. The most common radiological sign is a filling defect (Figure 76.50). Occasionally, irregularity of the bladder wall may herald the presence of an invasive tumour. Hydronephrosis may occur if a superficial tumour grows up the intramural ureter or if direct invasion of the ureteric wall occurs. Ultrasound scanning should be carried out if the kidney is non-functioning to determine its presence and the possibility of an obstructed system.

Cross-sectional imaging

Non-contrast CT or magnetic resonance (MR) imaging is being used in some centres instead of IVU or ultrasound scanning for the immediate management of patients with gross painless haematuria. For staging when a muscle-invasive bladder cancer is suspected, contrast-enhanced CT is used, ideally before TUR. False-positive pT3 disease can be diagnosed if cross-sectional imaging is carried out soon after TUR. Magnetic resonance imaging is being used more frequently (Figure 76.51) and can demonstrate lymph node metastasis or muscle invasion.

Cystourethroscopy

Cystourethroscopy is the mainstay of diagnosis and should always be performed on patients with haematuria. It can be carried out with a rigid instrument under general anaesthesia or with a flexible instrument under local anaesthesia. The urethra...
PART 12

THE URINARY BLADDER

is inspected at the initial insertion of the instrument (urethroscopy) and the bladder is then examined in a systematic fashion (cystoscopy). Conventional ‘white’ light cystoscopy has been improved recently by the introduction of photodynamic ‘blue’ light cystoscopy which relies on the photosensitiser hexamino-levulinate. It is now recommended in patients with high suspicion of the disease and negative initial findings and in follow up of patients with CIS.

Bimanual examination

A bimanual examination with the patient fully relaxed under general anaesthesia should be performed both before and after endoscopic surgical treatment of these tumours. The bladder should be empty. Once there is muscle invasion, the differentiation between pT2 and pT3 disease depends on whether a mass is palpable bimanually at the end of the procedure (pT3). When invasion has spread into the prostate in a man or the vagina in a woman, it is classified as pT4a. If the tumour is fixed to the lateral pelvic side wall, it is staged as pT4b.

TREATMENT FOR CARCINOMA OF THE BLADDER

Non-muscle invasive tumours

Endoscopic surgery

The tumour should be carefully resected in layers using a resectoscope. The base of the tumour is sent separately for histological examination. Small pinch biopsies are taken near to and distant from the primary lesion when CIS is suspected (inflamed or velvety appearance). After removal of the tumour, two or three further loops of tissue from the base should be sent separately so that the pathologist can accurately determine whether there is lamina propria or muscle invasion. The base of the tumour is then coagulated, so achieving haemostasis. The appearance of pale-yellow glistening fat will indicate a perforation of the bladder. Should this occur before the resection is complete, it may be prudent to stop the resection and leave a catheter in the bladder for a few days. In this instance, the procedure could be completed some 2 weeks later. The bimanual examination is repeated at the end of the endoscopic procedure. Following these procedures, an irrigating catheter is left in situ for 48 hours to prevent clot retention of urine. There is good evidence that a single dose of mitomycin (mitomycin C; 40 mg in 60 mL of fluid) instilled into the bladder before catheter removal decreases the risks of recurrence in patients with pTa and pT1 grade 1 and 2 disease.

Patients with larger solid tumours should have adequate material resected for histological staging and grading. If possible and straightforward, the mass of the tumour should be resected as completely as possible – even when pT2 or pT3 disease is suspected.

Follow up

Most urologists agree that patients with a single low- or medium-grade pTa tumour can safely be treated by resection alone plus a single instillation of mitomycin, followed up with regular cystoscopies.

The treatment of patients with multiple low- or medium-grade pTa tumours can be by either resection alone or resection followed by a 6-week course of intravesical chemotherapy with mitomycin, doxorubicin or epirubicin.

The treatment of pT1 disease is difficult. Approximately 30 per cent of tumours are understaged at first resection. For this reason, a repeat cystoscopy and resection of the tumour base is advocated within 6 weeks. Some urologists would offer immediate cystectomy to a patient with a high-grade pT1 tumour, particularly if it were multiple or accompanied by CIS, because of the 30–50 per cent risk of progression to muscle invasion. Others will treat such patients by endoscopy followed by immunotherapy with intravesical BCG. The most effective treatment of solitary medium-grade pT1 disease remains uncertain, but a reasonable approach would be endoscopic resection followed by resection of the area after 6 weeks, followed by intravesical BCG.

Follow-up cystoscopies are essential; they may be carried out under local anaesthesia with a flexible cystoscope or under general anaesthesia if the urologist feels that the patient is at high risk of recurrence. They should be performed at three-monthly intervals over the first year, following this the time interval between cystoscopies can be determined according to the presence or absence of further disease. In total, 30 per cent of patients will never develop another tumour so that, if the bladder has remained clear after two years, annual inspection
Treatment for carcinoma of the bladder

may be adequate. For patients who go on to develop multiple recurrences within the bladder at each examination, the cystoscopies need to be maintained at frequent intervals so that the growths can be resected. These patients are at a greater risk of their disease progressing; although intravesical chemotherapy can decrease the recurrence rate, no reduction in progression rates has been found.

Open surgical excision

This should be totally avoided. If by some error a bladder containing a tumour is entered, then the tumour may be removed with a diathermy needle and the base coagulated and the bladder closed. Postoperative radiotherapy to the wound will diminish the chance of tumour implantation.

Muscle-invasive tumours

The treatment of cancer with proven muscle invasion remains a subject for debate. Whatever the modality of treatment employed, few centres have five-year survival figures of more than 50 per cent. There is a move towards primary surgical treat-

ment in most centres. The use of systemic chemotherapy with a combination of agents – cisplatin, methotrexate, doxorubicin and vinblastine (M-VAC) or cisplatin plus gemcitabine given before (neoadjuvant) radical cystectomy – has been shown to be of benefit. The current evidence is that neoadjuvant chemotherapy improves survival by about 5–7 per cent.

Radiotherapy

External beam radiotherapy

External beam radiotherapy is usually given at 60 Gy over a 4- to 6-week period. There is a complete response rate of 40–50 per cent. Unfortunately, some patients do not respond and others exhibit only a partial response, with pTa or pT1 tumour remaining in the bladder giving rise to a risk of recurrence. Patients with residual disease after radiotherapy should be offered ‘salvage cystectomy’ if they are fit. Proponents of radiotherapy claim that it avoids the need to remove the bladder in some patients and allows men to retain potency. Radiotherapy is not without complications, and during the course of treatment will cause urinary frequency and also diarrhoea. Late complications can leave the bladder contracted and fibrosed, in which case it may need to be removed for palliative reasons. Late complications affecting the rectum should be uncommon, especially if lateral fields of irradiation are employed.

Surgery

Partial cystectomy

This should be limited to the treatment of small adenocarcinomas of the bladder.

Radical cystectomy and pelvic lymphadenectomy

This is now standard treatment for localised pT2–pT3 disease without evidence of secondary spread or of CIS that has not responded to BCG. Before contemplating radical surgery to remove the bladder, it is important to have evidence that surgical cure is attainable. Cross-sectional imaging of the pelvis may locally overstage the bladder if a recent resection has been carried out, although the finding of grossly enlarged pelvic, iliac or para-aortic nodes or liver metastases will alter the decision for cystectomy. A bone scan (using technetium-99m (99mTc)) will help to show whether there is spread to bone, and a chest plain x-ray should be performed to exclude pulmonary metastases, although many centres now perform routine CT imaging of the chest preoperatively and it tends to be more sensitive than plain x-ray in detecting small lung lesions.

Operation

Alternative drainage for urine is necessary following removal of the bladder. The standard procedure is to perform an ileal conduit diversion. Male patients should be counselled about the onset of erectile impotence and absent ejaculation following the operation, although in some cases the nerve supply for erectile function can be preserved through careful dissection; they should also be told about alternative forms of urinary diversion, which include continent urinary diversions and orthotopic bladder replacement.

Patients should be seen by a stoma care therapist, who will help to advise the patient and will try different ileostomy bags to ensure that the correct site is chosen, avoiding skin creases so that one does not end up with the disaster of a leaking urinary
ileostomy. A decision is made about whether the male urethra to be removed (depending on the estimated risk of recurrence within the urethra); a urethrectomy is usually indicated in patients with primary CIS or those with tumour invading the prostate stroma. Many surgeons are now offering total replacement of the bladder after cystectomy.

The patient should receive prophylactic antibiotics including metronidazole, cefuroxime and amoxicillin, and low-dose heparin or equivalent thrombo-embolic prophylaxis including physical means such as stockings and inatable devices applied to the legs peroperatively to promote venous circulation.

The abdomen is opened through a midline incision extending down to the symphysis pubis. The liver and the retroperitoneum are checked for evidence of metastases, and the operability of the bladder is assessed. A bilateral pelvic lymphadenectomy is performed, removing external iliac nodes, internal iliac nodes and the nodes in the obturator fossae. Some surgeons will remove lymph nodes up to the aortic bifurcation or higher with some evidence of improved long-term oncological outcomes. The vessels passing to the bladder from the side wall of the pelvis are ligated and divided; these include the obliterated hypogastric vessels, the superior vesical artery, the middle vesical veins, and the inferior vesical arteries and veins. The ureters are then divided. The posterior ligaments extending from the pararectal area to the back of the bladder are ligated and divided, and the layer posterior to Denonvilliers's fascia is opened up. The endopelvic fascia is then divided on each side and the puboprostatic ligaments are divided. A ligature is passed between the dorsal vein complex and the urethra, and the former is ligated and divided. The urethra is then mobilised and divided. The ligaments lateral to the prostate are divided and the bladder is removed. In women, the uterus and anterior vaginal wall need to be included. Women must be counselled about the loss of ovarian and uterine function.

An isolated loop of ileum is then prepared on its own mesentery, and continuity of the small bowel restored. The ureters are then implanted into the bowel segment and the ileostomy is created. Metabolic care must be taken to close all mesenteric windows, thus avoiding internal hernias. If the bladder is to be replaced orthotopically, a reservoir made from detubularised bowel (usually a segment of well vascularised ileum) is created and anastomosed to the urethra after implantation of the ureters.

The operative mortality rate associated with cystectomy is well established and associated with a low complication rate of less than 10 per cent. The main complications include urethral recurrence (about 5–8 per cent), which is increased in the presence of multifocal tumours, CIS and, particularly, invasion of prostatic stroma (Figure 76.52).

Leukoplakia

This condition is simply squamous metaplasia of the bladder. Profuse production of keratin may result in the passing of white particles in the urine. It cannot be treated easily. Localised areas may be resected endoscopically. Diffuse leukoplakia of the bladder is pre-malignant and results in squamous cancer of the bladder. Careful cystoscopic assessment is required and the condition may require cystectomy.

Endometriosis

Endometriosis within the bladder wall is rare but can have the appearance of a vascular bladder tumour or a tumour that contains chocolate-coloured or bluish cysts. The swelling enlarges and bleeds during menstruation. If medical management fails, by means of danazol or luteinising hormone-releasing hormone (LHRH) agonists, further treatment is usually by means of partial cystectomy or full-thickness endoscopic resection, depending on its site. The condition may be part of more widespread disease. Endometriosis is also a cause of ureteric stricture.

**INTERNAL AND EXTERNAL URINARY DIVERSION**

**Indications**

Diversion of the urine may be either a temporary expedient to relieve distal obstruction or a permanent procedure when the bladder has been removed or has lost normal neurological control and in cases of incurable fistula or irreparable obstruction.

**Methods of urinary diversion**

Temporary methods use prosthetic materials, the most common being a urinary catheter. In elderly patients unfit for prostatectomy, and in some patients with terminal carcinoma of the prostate, an indwelling silicone urethral Foley catheter changed every three months is a satisfactory method of drainage. A suprapubic placement is an alternative to urethral placement. The major drawback of long-term catheterisation is infection secondary to the associated bacteriuria that invariably develops. Ureteric obstruction can be relieved by placement of internal ‘double-J’ pigtail ureteric stents, which can remain for 4–5 months, but are usually changed every three months. As an alternative, a nephrostomy tube, inserted percutaneously by ultrasound and fluoroscopic imaging, is effective when internal stent placement is not feasible.

**Permanent urinary diversion**

**External diversion**

**Ileal conduit**

Permanent urinary tract diversion is most commonly performed by conduit diversion. The ureters are implanted into a short, isolated segment of ileum (Figure 76.53a) or, less commonly, colon. The conduit diverts the urine onwards to a cutaneous stoma for collection in an ileostomy bag. This form of diversion is well established and associated with a low complication rate of less than 10 per cent. The main complication is ureterointestinal stricture, which can be limited by spatulation of the distal ureters and an end-to-end anastomosis as described by Wallace (Figure 76.53a). Stenosis at the ileocutaneous site is

---

**Figure 76.52** Urethrectomy specimen from a patient who has previously undergone a radical cystectomy showing new transitional cell tumour formation in the urethra.

---

**Charles Pierre Denonvilliers**, 1808–1872, Professor of Anatomy, and later of Surgery, Paris, France.
less frequent, and a short isoperistaltic conduit limits the formation of a residual urine volume, reducing infection and avoiding the problems of reabsorption of urine. In some cases, when the pelvic area has been subjected to radiation, the lower ureters may be unhealthy; a high division with insertion of the ureters into an ileal loop above the root of the mesentery may then be wiser (Figure 76.54).

The site for the stoma must be chosen before operation, in consultation with a stoma care therapist; the site is marked indelibly on the skin.

Operative details
A coil of ileum, approximately 15–20 cm long and 30 cm from the ileocaecal valve, with its blood supply intact, is isolated. The left ureter is brought behind the mesorectum. The ureters may be joined to the ileum either end-to-side or end-to-end after anastomosing of the distal spatulated ureters to form a plate (Wallace). The distal end of the coil is brought out through an incision made at the site identified before operation; a disc of skin and fat is removed, a cruciate incision is made in the fascia and the muscle is split. The stoma is made about 2–3 cm long. It is evaginated initially by means of four sutures passing through the skin, the ileal loop as it passes through the opening and the cut edge of the ileum.

Internal urinary diversion

Colon and rectum
The advantage of diverting urine into the colon is that no collecting apparatus is necessary. Clearly, however, the anal sphincter must be competent. Before ureterosigmoidostomy is undertaken, the patient must prove that he or she can control at least 200 mL of fluid in the rectum. The disadvantage of the operation is that the renal tract is exposed continuously to infection from the faeces; this can be minimised by constructing an anti-reflux procedure. Various diversions are described; the Mainz II ureterosigmoidostomy creates a cul-de-sac type low-pressure reservoir in the sigmoid into which the ureters are placed (see Figure 76.53b). This reduces reflux, and bowel content, although in contact with urine, takes a direct route to the rectum. In the long term, cancer can develop at long-standing ureterocolic junctions (Figure 76.55).

Bladder reconstruction
Over the past decade, several techniques have been developed to allow a near-spherical urinary reservoir to be formed out of various lengths of bowel that are detubularised. These may consist of ileum, ileum and caecum or sigmoid colon (see Figure 76.53c). The ureters can then be reimplanted in these reservoirs in an anti-reflux manner and the reservoir anastomosed to the membranous urethra in the male (see Figures 76.20, 76.21 and 76.22). This is only indicated when the urethra can be preserved, with no evidence of tumour at the junction between the urethra and the prostate in the male, and bladder neck in the female. About 15–30 per cent of patients cannot empty the neobladder completely and will need to perform intermittent self-catheterisation. The results are good after radical cystectomy, particularly in younger well motivated patients.

Continent urinary diversion
A similar concept is used in the construction of continent diversions. A urinary reservoir is made as described above and the

David Mitchell Wallace, 1913–1992, urologist, St Peter’s Hospital, London, UK.
ureters are attached to the reservoir. A continence mechanism is then made to connect the reservoir to the skin. This is the complication-prone part of the operation. The continence mechanism may be made of an invaginated loop of ileum supported by three rows of staples (Kock pouch) or from the appendix, buried in an anti-reflux manner in a submucosal tube (Mitrofanoff; Figure 76.56). Alternatively, a length of ileum can be made into a tube (of a similar size to the appendix) after excision of the antimesenteric ileum and buried in a submucosal tunnel in an antireflux way. Clearly, these operations are complex, with the potential for increased postoperative complications.

**Bladder substitution and augmentation**

In patients with contraction of the bladder because of tuberculosis or with neuropathic dysfunction and a small bladder capacity, the bladder may need to be augmented. Similar techniques to those used to perform a bladder replacement can be utilised to make a near-spherical pouch from detubularised bowel, which can then be attached to the trigone or bladder neck after a near-total cystectomy (see Figures 76.20, 76.21 and 76.22). The ureters are then reimplemented. The facility to provide a continence mechanism must be available if needed in the neuropathic patient. This may comprise an artificial urinary sphincter or a colposuspension in the female.

**Complications of internal diversion**

**Stricture**

Uretersigmoidostomy was first used by Chaput in 1894. Subsequent modifications included those made by Coffey and Grey Turner. In these methods, the ureters were cut obliquely and pulled into the gut by a stitch – the ends were not stitched to the gut wall – and stenosis was common. Nesbit, Cordonnier and Leadbetter all recognised that these strictures could be prevented by anastomosing mucosa to mucosa.

**Reflux of urine**

High-pressure activity within a segment of gut can cause reflux of potentially infected urine at high pressure to the kidneys. In the long term, this can cause renal impairment. The principle of a low-pressure reservoir for both neobladder and ureterosigmoidostomy (Mainz II) reduces this. In addition, an anti-reflux mechanism, used in neobladder construction, is created by anastomosing the ureters to a non-detubularised 20-cm segment of small bowel, which is in continuity with the neobladder (see Figure 76.53c).

**Metabolic consequences of internal diversion**

**Resorption of solutes**

This depends upon the following factors: (1) the area of bowel that is exposed to urine; and (2) the length of time that the urine is in contact with the bowel epithelium.

The biochemical changes associated with urinary diversion are due to a combination of reabsorption of chloride and urea and progressively diminishing tubular function as a result of pyelonephritis. Diarrhoea with loss of potassium-containing mucus may exacerbate the loss of potassium. The typical changes of a hyperchloiraemic acidosis with potassium depletion occur more frequently with uretersigmoid divertion than with a colonic and ileal neobladder. When severe, the patient develops loss of appetite, weakness, thirst and diarrhoea. Coma may ensue. Mild acidosis, unrecognised over a long period, produces osteomalacia. Bone pain and even pathological fracture can occur. Renal impairment from pyelonephritis and reabsorption from the mucosa are seen less frequently after ileal or colonic conduit formation, continent urinary diversion or orthotopic bladder substitution. In fact, they are seen very infrequently except in patients with pre-existing renal impairment and unsatisfactory emptying of the urinary reservoir. Malabsorption can occur with the loss of terminal ileum and small bowel. The loss of terminal ileum can result in vitamin B12 deficiency and so monitoring of vitamin B12 and folate is recommended after the first year.

**Treatment**

Patients should be instructed to empty the rectum or conti-
nent reservoir or neobladder 3-hourly by day. In patients who have undergone ureterosigmoidostomy and in whom acidosis is present, a rectal tube should be inserted at night to drain the urine continuously. The patient should take a mixture of potassium citrate and sodium bicarbonate three times a day (2 g of each, either as crystals or as tablets). Regular serum biochemical analyses, including calcium, are required.

Established hyperchloraemic acidosis is usually associated with marked dehydration and the mainstay of treatment is administration of intravenous saline. The patient may be given small doses of sodium bicarbonate to half-correct the pH deficit if it is severe and additional intravenous potassium. This should be coupled with appropriate systemic antibiotic treatment.

**Risk of malignancy**

There is a risk of cancer developing in bowel used to reconstruct the urinary tract. When the urine is not mixed with faeces, the incidence is small, becoming significant after 15–18 years. The major risk of malignancy was discovered when ureterosigmoidostomy construction enabled free mixing of urine and faeces. The development of sigmoid reservoirs into which the ureters are inserted has reduced this risk.

The prostate and seminal vesicles

LEARNING OBJECTIVES

To understand:
- The relationship of anatomical structure and biochemical function to the development and treatment of benign and malignant disease of the prostate
- The terminology used to describe lower urinary tract symptoms and to know their causes as well as the treatment options available
- Which investigations are appropriate for carcinoma of the prostate
- Clinical staging of carcinoma of the prostate and how staging contributes to the complex decision-making process for the best treatment option

EMBRYOLOGY

From the primitive urethra, a series of solid epithelial buds develop and become canalised in a matter of weeks. The surrounding mesenchyme forms the muscular and connective tissue of the gland and has a major role in differentiation (stromal epithelium interactions). Skene's tubules, which open on either side of the female urethra, are the homologue of the prostate.

SURGICAL ANATOMY

The contemporary classification of the prostate into different zones was based on the work of McNeal (Figure 77.1). He showed that it is divided into the peripheral zone (PZ), which lies mainly posteriorly and from which most carcinomas arise, and a central zone (CZ), which lies posterior to the urethral lumen and above the ejaculatory ducts as they pass through the prostate; the two zones are rather like an egg in an egg-cup. There is also a periurethral transitional zone (TZ), from which most benign prostatic hyperplasia (BPH) arises. Smooth muscle cells are found throughout the prostate but, in the upper part of the prostate and bladder neck, there is a separate sphincter muscle that subserves a sexual function, closing during ejaculation. Resection of this tissue during prostatectomy is responsible for retrograde ejaculation. The transitional zone is the area from which most benign prostatic hyperplasia (BPH) arises.

Figure 77.1 Sagittal diagram of the prostate just lateral to the urethra showing the division into the different zones described by McNeal. The transitional zone is the area from which most benign prostatic hyperplasia (BPH) arises.

The glands of the peripheral zone (Figure 77.2), lined by columnar epithelium, lie in the fibromuscular stroma, and their ducts, which are long and branched, open into posterolateral grooves on either side of the verumontanum. The glands of the CZ and TZ are shorter and unbranched. All these ducts, the common ejaculatory ducts and the prostatic utricle open into the prostatic urethra.

Benign prostate hypertrophy starts in the periurethral transitional zone and, as it increases in size, it compresses the outer PZ of the prostate, which becomes the false capsule. There is also the outer true fibrous anatomical capsule, and external to this lie condensations of endopelvic fascia known as the periprostatic sheath of endopelvic fascia. Between the anatomical capsule and the prostatic sheath lies the abundant prostatic venous plexus. The prostatic sheath is contiguous with the fascia of Denonvilliers, which separates the prostate and its coverings from the rectum. The neurovascular bundles supplying autonomic innervation to the corpora of the penis are in very close vicinity of the prostate.

Alexander Johnston Chalmers Skene, 1828–1900, Professor of Gynecology, Long Island Hospital, Brooklyn, New York, NY, USA.
relationship to the posterolateral aspect of the prostatic capsule and are at risk of damage during radical cystoprostatectomy or radical prostatectomy; inadvertent diathermy in the region of these nerves may be the cause of uncommon erectile impotence after transurethral prostatectomy.

**PHYSIOLOGY**

The prostate has a sexual function, but it is unclear how important its secretions are to human fertility. That the normal adult prostate undergoes atrophy after castration was known to John Hunter.

**Systemic hormonal influences (endocrine) and local growth factors (paracrine and autocrine)**

The growth of the prostate is governed by many local and systemic hormones whose exact functions are not yet known. The main hormone acting on the prostate is testosterone, which is secreted by the Leydig cells of the testes under the control of luteinising hormone (LH), itself secreted from the anterior pituitary under the control of hypothalamic luteinising hormone-releasing hormone (LHRH). LHRH has a short half-life and is released in a pulsatile manner. This pulsatile release is important, as receptors for LHRH will become desensitised if permanently occupied. The administration of LHRH analogues in a continuous, non-pulsatile manner exploits the concept of receptor desensitisation and forms the basis for androgen deprivation therapy in prostate cancer. Testosterone is converted to 1,5-dihydrotestosterone (DHT) by the enzyme 5α-reductase, which is found in high concentration in the prostate and the perigenital skin (type II). Other androgens are secreted by the adrenal cortex, but their effects are minimal in the normal male. Oestrogenic steroids are also secreted by the adrenal cortex and, in the ageing male, may play a part in disrupting the delicate balance between DHT and local peptide growth factors, and hence increase the risk of BPH. Increased levels of serum oestrogens, by acting on the hypothalamus, decrease the secretion of LHRH (and hence LH) and thereby decrease serum testosterone levels. Thus, pharmacological levels of oestrogens cause atrophy of the testes and prostate by means of reductions in testosterone.

Other locally acting peptides are secreted by the prostatic epithelium and mesenchymal stromal cells in response to steroid hormones. These include epidermal growth factor, insulin-like growth factors, basic fibroblast growth factor and transforming growth factors alpha and beta. These undoubtedly play a part in normal and abnormal prostatic growth, but as yet their functions are unclear (Summary box 77.1).

**Elaboration and secretion of prostate-specific antigen and acid phosphatases**

Prostate-specific antigen (PSA) is a glycoprotein that is a serine protease. Its function may be to facilitate liquefaction of semen, but it is a marker for prostatic disease. It is measured by an immunoassay, and the normal range can differ a little from laboratory to laboratory. There is no real normal upper limit. The levels increase with age, with prostate cancer and with BPH. There are age-related values but, in general, in men aged 50–69 years, a level of about 3–4 ng/mL would prompt a discussion about the need for prostate biopsy. Its level in men with metastatic prostate cancer is usually increased to >30 ng/mL and falls to low levels after successful androgen ablation. Men with locally confined prostate cancer usually have serum PSA levels <10–15 ng/mL. Although PSA is a reliable marker for the progression of advanced disease, it is neither specific nor sensitive in the differential diagnosis of early prostate cancer and BPH, as both diseases are compatible with PSA in the range of 3–15 ng/mL. PSA measurement has superseded measurement of serum acid phosphatase. In summary, about 25 per cent of men with a PSA of 4–10 ng/mL have prostate cancer (i.e. it is not very specific), and about 15–20 per cent of men with a PSA of 1–4 ng/mL have prostate cancer. In general, one would advise men aged 50–69 years to undergo prostate biopsy if the PSA was more than ~3 ng/mL. The threshold would be lower in younger men with a strong family history.

**BENIGN PROSTATIC HYPERPLASIA**

**Aetiology of benign prostatic hyperplasia**

**Hormones**

Serum testosterone levels slowly but significantly decrease with advancing age; however, levels of oestrogenic steroids are not decreased equally. According to this theory, the prostate enlarges because of increased oestrogenic effects. It is likely that the secretion of intermediate peptide growth factors plays a part in the development of BPH (Summary box 77.2).
Pathology

BPH affects both glandular epithelium and connective tissue stroma to variable degrees. These changes are similar to those occurring in breast dysplasia (see Chapter 53), in which adenosis, epitheliosis and stromal proliferation are seen in differing proportions. BPH typically affects the submucous group of glands in the transitional zone, forming a nodular enlargement. Eventually, this overgrowth compresses the PZ glands into a false capsule and causes the appearance of the typical ‘lateral’ lobes.

When BPH affects the subcervical CZ glands, a ‘middle’ lobe develops that projects up into the bladder within the internal sphincter (Figure 77.3). Sometimes, both lateral lobes also project into the bladder, so that, when viewed from within, the sides and back of the internal urinary meatus are surrounded by an intravesical prostatic collar.

Effects of benign prostatic hyperplasia

It is important to realise that the relationship between anatomical prostatic enlargement, lower urinary tract symptoms (LUTS) and urodynamic evidence of bladder outflow obstruction (BOO) is complex (Figure 77.4). Pathophysiologically, BOO may be caused in part by increased smooth muscle tone, which is under the control of α-adrenergic agonists (Summary box 77.3).

Anatomically, the effects are as follows:

- **Urethra.** The prostatic urethra is lengthened, sometimes to twice its normal length, but it is not narrowed anatomically. The normal posterior curve may be so exaggerated that it requires a curved catheter to negotiate it. When only one lateral lobe is enlarged, distortion of the prostatic urethra occurs.

- **Bladder.** If BPH causes BOO, the musculature of the bladder hypertrophies to overcome the obstruction and appears trabeculated (Figure 77.5). Significant BPH is associated with increased blood flow, and the resultant veins at the base of the bladder are apt to cause haematuria.

Lower urinary tract symptoms

In both sexes, non-specific symptoms of bladder dysfunction become more common with age, probably owing to impairment of smooth muscle function and neurovesical coordination. Not all symptoms of disturbed voiding in ageing men should therefore be attributed to BPH causing BOO. Urologists prefer the term LUTS and discourage the use of the descriptive term ‘prostatism’.

The following conditions can coexist with BOO, leading to difficulty in diagnosis and in predicting the outcome of treatment:

- idiopathic detrusor overactivity (see Chapter 76);

- neuropathic bladder dysfunction as a result of diabetes, strokes, Alzheimer’s disease or Parkinson’s disease (see Chapter 76);
Benign prostatic hyperplasia

1343

degeneration of bladder smooth muscle giving rise to impaired voiding and detrusor instability;
BOO due to BPH. LUTS can be described as:

- voiding
  - hesitancy (worsened if the bladder is very full);
  - poor flow (unimproved by straining);
  - intermittent stream – stops and starts;
  - dribbling (including after micturition);
  - sensation of poor bladder emptying;
  - episodes of near retention;
- storage
  - frequency;
  - nocturia;
  - urgency;
  - urge incontinence;
  - nocturnal incontinence (enuresis).

LUTS are usually assessed by means of scoring systems, which give a semi-objective measure of severity. However, some symptoms do not give an accurate picture of the underlying pathophysiological problem. For instance, a man with severe detrusor instability may void only small volumes and hence he will have a sensation of poor flow because low voided volumes (<100 mL) are associated with low flow rates.

Severe irritative symptoms are usually associated with detrusor instability. Post-micturition dribbling is now known not to be a consequence of BOO and is not usually improved by prostatectomy.

Bladder outflow obstruction

This is a urodynamic concept based on the combination of low flow rates in the presence of high voiding pressures. It can be diagnosed definitively only by pressure-flow studies. This is because symptoms are relatively non-specific and can result from detrusor instability, neurological dysfunction and weak bladder contraction. Even low measured peak flow rates (<10–12 mL/s) are not absolutely diagnostic because, in addition to BOO, weak detrusor contractions or low voided volumes (owing to instability) can be the cause. Nonetheless, flow rates provide a useful guide for everyday clinical management.

Urodynamically proven BOO may result from:

- Urinary flow rates decrease (for a voided volume >200 mL, a peak flow rate of >15 mL/s is normal (Figure 77.6), one of 10–15 mL/s is equivocal and one <10 mL/s is low (Figure 77.7).
- Voiding pressures increase (pressures >80 cmH₂O are high (Figure 77.8), pressures between 60 and 80 cmH₂O are equivocal and pressures <60 cmH₂O are normal).

The long-term effects of bladder outflow obstruction are as follows:

- The bladder may decompensate so that detrusor contraction becomes progressively less efficient and a residual urine develops.
- The bladder may become more irritable during filling with a decrease in functional capacity partly caused by detrusor overactivity (see Chapter 76), which may also be caused by neurological dysfunction or ageing, or may be idiopathic.

Aside from symptoms, the complications of BOO are as follows:

- Acute retention of urine is sometimes the first symptom of BOO. Postponement of micturition is a common precipitating cause; overindulgence in beer and confinement to bed on account of intercurrent illness or operation are other causes.
- Chronic retention. In patients in whom the residual volume is >250 mL or so (Figure 77.9), the tension in the bladder wall increases owing to the combination of a large volume of residual urine and increased resting and
filling bladder pressures (a condition known as high-pressure chronic retention). The increased intramural tension results in functional obstruction of the upper urinary tract with the development of bilateral hydronephrosis (Figures 77.10 and 77.11). As a result, upper tract infection and renal impairment may develop. Such men may present with overflow incontinence, enuresis and renal insufficiency. These symptoms should alert the doctor to the presence of this condition.

- Impaired bladder emptying. If the bladder decompensates with the development of a large volume of residual urine, urinary infection and calculi are prone to develop.
- Haematuria. This may be a complication of BPH. Other causes must be excluded by carrying out an intravenous urography (IVU), cystoscopy, urine culture and urine cytological examination.
- Other than pain from retention, pain is not a symptom of BOO, and its presence should prompt the exclusion of acute retention, urinary infection, stones, carcinoma of the prostate and carcinoma in situ of the bladder.

### ASSESSMENT OF THE PATIENT WITH LOWER URINARY TRACT SYMPTOMS

#### History

Symptom score sheets such as the International Prostate Symptom Score (IPSS) assign a score which gives information regarding the severity of symptoms at the outset and changes over time and following intervention. The IPSS assessment should include an assessment of quality of life, which is a reflec-
Assessment of the patient with lower urinary tract symptoms

1345

tion of the degree of ‘bother’ caused by a patient’s symptoms. In addition to the IPSS, a frequency-volume diary completed by the patient before attending the clinic is invaluable in revealing fluid intake habits, diurnal variation in outputs and low-volume, frequent voiding. These assessments are routinely performed at lower urinary tract clinics but can be elicited by a thorough clinical history (Summary box 77.4).

Summary box 77.4

Investigations of men with LUTS

Essential investigations
- Urine analysis by dipstick for blood, glucose and protein
- Urine culture for infection
- Serum creatinine
- Urinary flow rate and residual volume measurement

Additional investigations
- PSA if indicated
- Pressure-flow studies

Abdominal examination

Abdominal extension is usually normal. In patients with chronic retention, a distended bladder will be found on palpation, on percussion and sometimes on inspection with loss of the transverse suprapubic skin crease. General physical examination may demonstrate signs of chronic renal impairment with anaemia and dehydration. The external urinary meatus should be examined to exclude stenosis, and the epididymides are palpated for signs of inflammation.

Rectal examination

In benign enlargement, the posterior surface of the prostate is smooth, convex and typically elastic, but the fibrous element may give the prostate a firm consistency. The rectal mucosa can be made to move over the prostate. Residual urine may be felt as a fluctuating swelling above the prostate. It should be noted that, if there is a considerable amount of residual urine present, it pushes the prostate downwards, making it appear larger than it is.

The nervous system

The nervous system is examined to eliminate a neurological lesion. Diabetes mellitus, tabes dorsalis, disseminated sclerosis, cervical spondylosis, Parkinson’s disease and other neurological states may mimic prostatic obstruction. If these are suspected then a pressure-flow urodynamic study should be carried out to diagnose BOO. Examination of perianal sensation and anal tone is useful in detection of an S2 to S4 cauda equina lesion.

Serum prostate-specific antigen

The difficulty here is the uncertain benefit of early detection and radical treatment of prostate cancer – this is dealt with in the section on prostate cancer. Certainly, men should be informed about the test, the risks of the prostate biopsy that might be required and the risks of the detection of a cancer that we are not certain how best to treat, as well as the positive aspects of the early discovery of a small prostate cancer. After suitable counselling, measurement of serum PSA may be helpful. Men in whom a diagnosis of early prostate cancer might influence treatment option (such as those under 70 years or those with a positive family history who might be offered radical treatment) should be offered a PSA measurement. If this is in excess of 2.5–4 nmol/L, then transrectal ultrasound scanning (TRUS) plus multiple transrectal biopsies (10 biopsies) should be considered.

If rectal examination is quite normal with no suspicion of cancer, and if no change in treatment policy would in any case result from the diagnosis of early prostate cancer, then there is little point in the routine measurement of PSA in men with uncomplicated BOO. However, because of the fear of future litigation, many find it easier to offer a PSA test.

Flow rate measurement

For this to be meaningful, two or three voids should be recorded, and the voided volume should be in excess of 150–200 mL. This usually means the patient attending a special flow rate clinic. A typical history and a flow rate <10 mL/s (for a voided volume of >200 mL; Figure 77.7) will be sufficient for most urologists to recommend treatment. Usually, a flow rate measurement will be coupled with ultrasound measurement of post-void residual urine.

There are pitfalls in the measurement of flow rates. The machine must be accurately calibrated. The patient must void volumes in excess of 150 mL, and two or three recordings are needed to obtain a representative measurement. Decreased flow rates and symptoms of prostatism may be seen in:
- BOO;
- low voided volumes (characteristically in men with detrusor instability);
men with weak bladder contractions (low pressure-flow voiding).

**Pressure-flow urodynamic studies**
Details of these studies are outlined in Chapter 76 (see Figure 77.8). They should be performed on the following patients:

- men with suspected neuropathy (Parkinson’s disease, dementia, longstanding diabetes, previous strokes, multiple sclerosis);
- men with a dominant history of irritative symptoms and men with lifelong urgency and frequency;
- men with a doubtful history and those with flow rates in the near normal range (~ or >15 mL/s);
- men with invalid flow rate measurements (because of low voided volumes).

**Blood tests**
Serum creatinine, electrolytes and haemoglobin should be measured.

**Examination of urine**
The urine is examined for glucose and blood; a midstream specimen should be sent for bacteriological examination, and cytological examination may be carried out if carcinoma in situ is thought possible.

**Upper tract imaging**
Most urologists no longer carry out imaging of the upper tract in men with straightforward symptoms. Obviously, if infection or haematuria is present, then the upper tract should be imaged by means of intravenous urogram or ultrasound scan.

**Cystourethroscopy**
Inspection of the urethra, the prostate and the urothelium of the bladder should always be done immediately prior to prostatectomy, whether it is being done transurethrally or by the open route to exclude a urethral stricture, a bladder carcinoma and the occasional non-opaque vesical calculus. The decision of whether to perform prostatectomy must be made before cystoscopy. This should be based on the patient’s symptoms, signs and investigations. Direct inspection of the prostate is a poor indicator of BOO and the need for surgery.

**Transrectal ultrasound scanning**
There is no need to carry this out routinely. Accurate estimation of prostatic size is also possible by means of transrectal or transabdominal ultrasound scan.

**Management of men with benign prostatic hyperplasia or bladder outflow obstruction**

**Acute retention** (see Chapter 76) in fit men with no other cause for retention (drugs, constipation, recent operation, etc.) (accounts for 25 per cent of prostatectomies).

**Chronic retention and renal impairment:** a residual urine of 200 mL or more, a raised blood urea, hydroureter or hydronephrosis demonstrated on urography and uraemic manifestations (accounts for 15 per cent of prostatectomies).

**Complications of bladder outflow obstruction:** stone, infection and diverticulum formation.

**Haemorrhage:** occasionally, venous bleeding from a ruptured vein overlying the prostate will require prostatectomy to be performed.

**Elective prostatectomy for severe symptoms:** this accounts for about 60 per cent of prostatectomies. Increasing difficulty in micturition, with considerable frequency day and night, delay in starting and a poor stream are the usual symptoms for which prostatectomy is advised. Frequency alone is not a strong indication for prostatectomy. The natural progression of outflow obstruction is variable and rarely gets worse after ten years. Severe symptoms, a low maximum flow rate (<10 mL/s) and an increased residual volume of urine (100–250 mL) are relatively strong indications for operative treatment. The exact cut-off for operative or non-operative treatment will depend on careful discussion between the patient and the urologist (Summary box 77.5).

**Acute retention**
The management of retention is discussed in detail in Chapter 76. Once the bladder has been drained by means of a catheter, the patient’s fitness for treatment is determined. If retention was not caused by drugs or constipation, then prostatectomy would usually be the correct management. Unfit men or those with dementia may be treated by means of indwelling prostatic stents or a catheter. Similar comments apply to men with chronic retention once renal function has been stabilised by catheterisation. The role of α-adrenergic drugs followed by a trial of catheter has been tested and found to be successful in certain groups with a short history and a low residual volume of urine, but the recurrence rate becomes cumulatively high.

**Special problems in the management of chronic retention**
Men with chronic retention who have relatively low volumes of residual urine and who do not have symptoms suggestive of coexistent infection and with good renal function do not necessarily require catheterisation before proceeding to prostatectomy on the next available list. For those who are uraemic, urgent catheterisation is mandatory to allow renal function to recover and stabilise. Haematuria often occurs following catheterisation owing to collapse of the distended bladder and upper tract, but settles within a couple of days (see Chapter 76 for general management of retention).
Uraemic patients with chronic retention are often dehydrated at the time of admission. Owing to the chronic back pressure on the distal tubules within the kidney, there is loss of the ability to reabsorb salts and water. The result, following release of this pressure, may be an enormous outflow of salts and water, which is known as post-obstructive diuresis. It is for this reason that a careful fluid chart, daily measurements of the patient's weight and serial estimations of creatinine and electrolytes are essential. Intravenous fluid replacement is required if the patient is unable to keep up with this fluid loss. These patients are often anaemic and may require a blood transfusion once fluid balance is stabilised (if haemoglobin is <9 g/L).

**Indications for elective treatment in men with LUTS secondary to BPH**

Following careful assessment (see above under Assessment of the patient with lower urinary tract symptoms), the following questions should be answered:

1. Have they failed a preliminary trial of medical therapy? Commonly, men will have been treated with α-blockers or 5α-reductase inhibitors and will have failed treatment. They are then referred by their general practitioner to the urologist.
2. Is BOO present? In many cases, the findings of significant symptoms (assessed by symptom scoring), a benign prostate supplemented by the finding of a low maximum flow rate (<10–12 mL/s for a good voided volume (>200 mL)) will suffice to make a reasonable working diagnosis of BOO. In some men, particularly those with irritative symptoms, suspected neurological disease or those with technically imperfect flow rate measurements, pressure–flow studies will need to be performed.
3. How severe are the symptoms and what are the risks of doing nothing? Severe symptoms and a large residual volume of urine will usually require treatment. Men with mild symptoms, good flow rates (>15 mL/s) and good bladder emptying (residual urine <100 mL) may be safely managed by reassurance and review: such patients rarely develop severe complications such as retention in the long term.
4. Is the man fit for operative treatment?
5. What treatments are available, what are the outcomes and do the side-effects justify treatment?

**Treatment**

**Men with symptoms attending for elective treatment (excluding acute and chronic retention)**

**Conservative treatment**

It is in men with relatively mild symptoms, reasonable flow rates (>10 mL/s) and good bladder emptying (residual urine <100 mL) that careful discussion over the merits and side effects of operative treatment is warranted. Waiting for a period of six months after careful discussion of the diagnosis is indicated. After this, a repeat assessment of symptoms, flow rates and ultrasound scan is helpful; many men with stable symptoms will elect to leave matters be. Advice over limiting fluid intake in the evening and careful use of anti-muscarinics to help with irritative symptoms is also useful.

**Drugs**

In men who are very concerned about the development of sexual dysfunction after transurethral resection of the prostate (TURP), the use of drugs may be helpful. Two classes of drug have been used in the treatment of men with BOO. α-Adrenergic blocking agents inhibit the contraction of smooth muscle that is found in the prostate. The other class of drug is the 5α-reductase inhibitors, which inhibit the conversion of testosterone to DHT, the most active form of androgen. These drugs, when taken for a year, result in a 25 per cent shrinkage of the prostate gland. Both groups of drugs are effective; however, α-blockers work more quickly and, although the 5α-reductase inhibitors have fewer side effects, they need to be taken for at least six months, and their effect is greatest in patients with large (>50 g) glands. Drug therapy results in improvements in maximum flow rates by about 2 mL/s more than placebo and results in mild (20 per cent) improvement in symptom scores. TURP, however, results in improvements in maximum flow rates from 9 to 18 mL/s and a 75 per cent improvement in symptom scores. These drugs are expensive in comparison with their effectiveness, and a significant proportion of men who try these drugs will subsequently undergo TURP. They may be best targeted at men who have failed an initial trial of watchful waiting and who wish to avoid surgery for a period.

**Operative treatment**

Apart from the strong indications for operative treatment mentioned above, the most common reason for TURP is a combination of severe symptoms and a low flow rate <12 mL/s. The key is to assess symptoms carefully and to counsel men about side effects and likely outcome before advising operative treatment.

**Counselling men undergoing prostatectomy**

Men undergoing prostatectomy need to be advised about the following:

- **Retrograde ejaculation.** This occurs in about 65 per cent of men after prostatectomy.
- **Erectile impotence.** This occurs in about 5 per cent of men, usually those whose potency is waning.
- **The success rate.** On the whole, men with acute and chronic retention do well from the symptomatic point of view. Ninety per cent of men undergoing elective operation for severe symptoms and urodynamically proven BOO do well in terms of symptoms and flow rates. Only about 65 per cent of those with mild symptoms or those with weak bladder contraction as the cause of their symptoms do well. Men with unobstructed detrusor instability do not respond well to TURP. This is the reason for carefully documenting the severity of symptoms and flow rates (supplemented when necessary by pressure–flow studies) before deciding on treatment.
- **The risk of reoperation.** After TURP, this is about 15 per cent after 8–10 years.
- **The morbidity rate.** Death after TURP is infrequent (<0.5 per cent), severe sepsis is found in about 6 per cent and severe haematuria requiring transfusion of more than two units of blood occurs in about 3 per cent. After discharge, about 15–20 per cent of men subsequently require antibiotic treatment for symptoms of urinary infection. Risk factors for complications include admission with retention, prostate cancer, renal impairment and advanced age.
Methods of performing prostatectomy

The prostate can be approached (1) transurethrally (TURP), (2) retropubically (RPP), (3) through the bladder (transvesical; TVP) or (4) from the perineum (Figure 77.12).

Transurethral resection of the prostate

TURP has largely replaced other methods unless diverticulectomy or the removal of large stones necessitates open operation; over 95 per cent of men being treated by urologists can be dealt with by TURP. Perhaps the greatest advance in the history of transurethral surgery was marked by the development of the rigid lens system of Professor Harold Hopkins. His lenses, illuminated by a fibreoptic light source, permit unparalleled visualisation of the working field. Men with indwelling catheters, those with recent urinary infection, those with chronic retention or those with prosthetic material or heart valves should receive broad spectrum prophylactic antibiotics with amoxicillin plus cefuroxime or gentamicin intravenously at induction of anaesthesia.

Strips of tissue are cut from the bladder neck down to the level of the verumontanum (Figure 77.13). Cutting is performed by a high-frequency diathermy current, which is applied across a loop mounted on the hand-held trigger of the resectoscope. Coagulation of bleeding points can be accurately achieved, and damage to the external sphincter is avoided provided one uses the verumontanum as a guide to the most distal point of the resection. The ‘chips’ of prostate are then removed from the bladder using an Ellik evacuator. The risks of hyponatraemia are reduced by using 1.5 per cent isotonic glycine for irrigation, and the recent introduction of continuous-flow resectoscopes makes the procedure swift and safe in experienced hands. At the end of the procedure, careful haemostasis is performed, and a three-way, self-retaining catheter irrigated with isotonic saline is introduced into the bladder to prevent any further bleeding from forming blood clots. Irrigation is continued until the outflow is pale pink, and the catheter is usually removed on the second or third postoperative day. In men with small prostates or bladder neck dyssynergia or stenosis, it is better to divide the bladder neck and prostatic urethra with a diathermy ‘bee-sting’ electrode.

Retropubic prostatectomy (Millin)

Using a low, curved transverse suprapubic Pfannenstiel incision, which includes the rectus sheath, the recti are split in the midline and retracted to expose the bladder. With the patient in the Trendelenburg position, the surgeon separates the bladder and the prostate from the posterior aspect of the pubis. In the space thus obtained, the anterior capsule of the prostate is incised with diathermy below the bladder neck, care being taken to obtain complete control of bleeding from divided prostatic veins by suture ligation. The prostatic adenoma is exposed and enucleated with a finger. A wedge is taken out of the posterior lip of the bladder neck to prevent secondary stricture in this region. The exposure of the inside of the prostatic cavity is good, and control of haemorrhage is achieved with diathermy and suture ligation of bleeding points before closure of the capsule over a Foley catheter (inserted per urethram) draining the bladder.

Transvesical prostatectomy

The bladder is opened, and the prostate enucleated by putting a finger into the urethra, pushing forwards towards the pubes to separate the lateral lobes, and then working the finger between the adenoma and the false capsule. In Freyer’s operation (1901), the bladder was left open widely and drained by

Figure 77.12 The surgical approaches to the prostate.

Figure 77.13 Endoscopic photograph of transurethral prostatectomy.

Terence John Millin, 1903–1980, surgeon, The Westminster Hospital, London, UK; described the operation of retropubic prostatectomy in 1945. Honorary surgeon, All Saints’ Hospital for Genitourinary Diseases, London, UK; he was regarded as ‘the greatest of Irish urologists’ and ‘the pioneer of the retropubic space’. To facilitate his operation, he devised a self-retaining retractor that goes by his name and the ‘boomerang’ needle to close the prostatic capsule. He used to be invited all over the world to operate on VIPs. He was a former President of the Royal College of Surgeons in Ireland. He gave up operating at the age of 57 to enjoy his farm in County Wicklow where he died of laryngeal carcinoma. He played international rugby for Ireland.

Sir Peter Johnston Freyer, 1852–1921, an Irish born surgeon who performed the first successful prostatectomy in 1900 at St Peter’s Hospital, London. He used to give a running commentary to his visiting surgeons in French and Hindustani. Surgeon, St Peter’s Hospital for Stone, London, UK.
a suprapubic tube with a 16-mm lumen in order to allow free drainage of blood and urine. Harris (1934) advocated control of the prostatic arteries by lateral stitches inserted with his boomerang needle, the bladder wall was closed and the wound drained.

**Perineal prostatectomy (Young)**

This has now been abandoned for the treatment of BPH.

**After treatment**

Most urologists irrigate the bladder with sterile saline by means of a three-way Foley catheter for 24 hours or so.

**Complications**

**Local**

Haemorrhage is a major risk following prostatectomy whatever the surgical approach. Care should be taken in diathermising arterial bleeding points after TURP; they are often better seen when the rate of inflow of fluid is decreased. In the recovery room, one should check that the bladder is draining adequately; if it is not, this may indicate that a clot is blocking the eye of the catheter. The bladder should be promptly washed out using strict aseptic technique. The catheter should be changed by the surgeon. Only rarely is it necessary to return the patient to the operating room.

Secondary haemorrhage tends to occur after the patient has been discharged. All men should be warned about this possibility and given appropriate advice to rest and to have a high fluid intake. It is usually minor in degree but if clot retention occurs, the patient will need to be readmitted; a catheter will have to be passed and the bladder washed out.

Perforation of the bladder or the prostatic capsule can occur at the time of transurethral surgery. This usually occurs from a combination of inexperience in association with a large prostate or heavy blood loss. If the field of vision becomes obscured by heavy blood loss, it is often prudent to achieve adequate haemostasis and abandon the operation, swallowing one’s pride on the understanding that a second attempt may be necessary. A large perforation with marked extravasation may require the insertion of a small suprapubic drain. Rectal perforation should be extremely rare.

**Sepsis**

Bacteraemia is common even in men with sterile urine and occurs in over 50 per cent of men with infected urine, prolonged catheterisation or chronic retention. Septicaemia can occur in these patients shortly after operation or when the catheter is removed. In men at high risk, the use of prophylactic antibiotics is recommended. Wound infection following open prostatectomy is common if a urethral catheter has been in situ for a number of days before the operation. The most worrying aspect of infection is the early rigor following surgery. If left undetected and untreated, this may progress to frank septicemia with profound hypotension. A blood culture should be taken and broad spectrum antibiotics with Gram-negative activity given parenterally, e.g. augmentin and gentamicin.

**Incontinence**

Incontinence is inevitable if the external sphincter mechanism is damaged. The bladder neck is rendered incompetent by any prostatectomy and, therefore, an intact distal sphincter mechanism is essential for continence. Damage to the sphincter may occur at open prostatectomy and following transurethral surgery if the resection extends beyond the verumontanum. If pelvic floor physiotherapy is ineffective, then the only satisfactory treatment is the fitting of an artificial urinary sphincter. In some patients, detrusor instability contributes to the incontinence. The use of anti-cholinergic agents or imipramine or duloxetine may help.

**Retrograde ejaculation and impotence**

Impotence in men with good sexual function before surgery is uncommon, but retrograde ejaculation occurs commonly (>50 per cent) because of disruption to the bladder neck mechanism.

**Urethral stricture**

This may be secondary to prolonged catheterisation, the use of an unnecessarily large catheter, clumsy instrumentation or the presence of the resectoscope in the urethra for too long a period. These strictures arise either just inside the meatus or in the bulbous urethra. An early stricture can usually be managed by simple bouginage but, later on, it may be necessary to cut the densely fibrotic stricture with the optical urethrotome. The routine use of an Otis urethrotomy prior to TURP reduces the incidence of postoperative stricture.

**Bladder neck contracture**

Occasionally, a dense fibrotic stenosis of the bladder neck occurs following overaggressive resection of a small prostate. It may be due to the overuse of coagulating diathermy. Transurethral incision of the scar tissue is necessary.

**Reoperation**

It is now well known that, after eight years, 15–18 per cent of men with BPH will undergo repeat TURP (the rate after open prostatectomy is about 5 per cent). The reasons include a technically imperfect primary procedure and a speculative repeat operation in men with symptoms who are cystoscoped after operation.

**General complications**

Death occurs in about 0.2–0.3 per cent of men undergoing elective prostatectomy. In very elderly men, in men with prostate cancer admitted as an emergency with acute or chronic retention or in those with very large prostates, the 30-day death rate may be in the order of 1 per cent.

**Cardiovascular**

Pulmonary atelectasis, pneumonia, myocardial infarction, congestive cardiac failure and deep venous thrombosis are all potentially life-threatening conditions that can affect this elderly and often frail group of men.

**Water intoxication (also known as TUR syndrome)**

The absorption of water into the circulation at the time of transurethral resection can give rise to congestive cardiac failure, hyponatraemia and haemolysis. Accompanying this, there is frequently confusion and other cerebral events often mimicking a stroke. The incidence of this condition has been reduced since the introduction of isotonic glycine for performing the
resections and the use of isotonic saline for postoperative irrigation. The treatment consists of fluid restriction.

**Osteitis pubis**
This is rare.

**Newer treatments**
In general, newer, minimally invasive treatments occupy a position intermediate between TURP and drug treatment. In the last decade, technological innovations led to the introduction of novel minimally invasive treatments for prostatectomy. Tissue ablative techniques using hyperthermia and laser energy were associated with minimal morbidity and could often be performed as outpatient procedures. Many of the initial studies reporting treatment success were poorly designed and over a short duration. Longer-term follow up and randomised controlled trials have failed to confirm significant benefit from these techniques. More recently, the holmium laser, a pulsed solid-state laser, has been used to enucleate the prostate adenoma. This approach involves excision of parts of the prostate using a cutting laser and then morcellating the excised prostate fragments, which fall back into the bladder so that they can be removed. Morbidity with this procedure is low and short-term results favourable; long-term follow up will be necessary to determine whether this treatment will have a role to play in the management of BOO. The green light laser is now being used to vaporise the prostate tissue, but has not yet been shown to be as durable as holmium laser treatment or TURP, because the amount of tissue removed is usually less. Recently, the development of bipolar resectoscopes, which allow irrigation with normal saline, has allowed the resection of larger prostates without the risk of causing water intoxication.

**Intraurethral stents**
These devices are possibly helpful in the management of men with retention who are grossly unfit (classified by the American Society of Anesthesiologists as ASA grade IV) (Figure 73.14). These men are rare cases.

**BLADDER OUTFLOW OBSTRUCTION CAUSED BY THE BLADDER NECK**

**Aetiology**
This condition usually occurs in men, but can rarely affect children of both sexes and women. It may be due to muscular hypertrophy or fibrosis of the tissues at the bladder neck following TURP.

**Clinical syndromes**

**Owing to muscle hypertrophy or dyssynergia**
Marion described a series of cases in which muscular hypertrophy of the internal sphincter in a young person had resulted in the development of a vesical diverticulum or hydronephrosis (Marion’s disease or ‘prostatism sans prostate’). It is thought that dyssynergic contraction of the smooth muscle of the bladder neck (bladder neck dysynergia) may account for some cases of BOO.

**Owing to fibrosis**
The symptoms are similar to those of prostatic enlargement but are a consequence of scarring after TURP.

**Treatment**
The management of these patients depends on achieving an accurate diagnosis. For this, urodynamic investigation is often necessary, which should demonstrate raised voiding pressures and diminished flow rate.

**Drugs**
The presence of α-adrenergic receptors in the region of the bladder neck and prostatic urethra allows pharmacological manipulation of the outflow to the bladder.

**α-Blocking drugs**
Alfuzosin, 2.5 mg bd to tds (to a total maximum of 10 mg/day), doxazosin, 1 mg nocte (up to a maximum of 8 mg/day), indoramin, 20 mg bd (increased to a total maximum of 100 mg/day in divided doses), prazosin 500 mg bd (maintenance up to 2 mg/day) and terazosin, 1 mg nocte (to a total maximum of 10 mg/day), can be very useful, causing relaxation of the bladder neck. Modified release tamsulosin 400 mg can be taken once daily. These drugs are not target specific, and patients must be warned of the possibility of postural hypotension.

**Transurethral incision**
Transurethral incision of the bladder neck is the operation of choice. Sometimes symptoms recur, but this is usually due to inadequate division of the fibres of the bladder neck.

**Congenital valves of the prostatic urethra**
See Chapter 78.

**PROSTATIC CALCULI**
Prostatic calculi are of two varieties: endogenous, which are common, and exogenous, which are comparatively rare.

An exogenous prostatic calculus is a urinary (commonly ureteric) calculus that becomes arrested in the prostatic urethra. This is considered in Chapter 75.

Endogenous prostatic calculi are usually composed of calcium phosphate combined with about 20 per cent organic material.

**Clinical features**
Prostatic calculi are usually symptomless, being discovered on
Carcinoma of the prostate

TRUS, on radiography of the pelvis, during prostatectomy or associated with carcinoma of the prostate or chronic prostatitis. In cases associated with severe chronic prostatic infection, the associated fibrosis and nodularity are difficult to differentiate from carcinoma. On radiographs or ultrasound scans, these stones are often seen to form a horseshoe (Figure 77.15) or a circle.

Treatment of prostatic calculi
They usually require no treatment.

Conservative measures
Associated chronic prostatic infection may be treated by means of ciprofloxacin or trimethoprim.

Transurethral resection
Transurethral resection will often release small calculi as the strips of prostatic tissue are excised. Others are passed per urethram at a later date.

Corpora amylaceae
Corpora amylaceae are tiny calcified lamellated bodies found in the glandular alveoli of the prostates of elderly men and apes, but not in the prostates of animals lower in the phylogenetic scale than anthropoids. Corpora amylaceae are probably the forerunners of endogenous prostatic calculi.

Carcinoma of the prostate

In 2008, 37,000 men were registered and 10,000 died from it; the corresponding figures in the USA were 186,000 and 28,000, respectively. If histological section of prostates at autopsy is performed, increasingly frequent foci of microscopic prostate cancers are found with increasing age. These foci of prostate cancer have variable potential for progressing clinically to metastatic disease. About 10–15 per cent of younger men who develop prostate cancer have a positive family history of the disease, but the aetiology is unclear. Throughout the world, rates of microscopic foci of prostate cancer are constant, but rates of clinically evident disease are low in men in Japan and China. Carcinoma of the prostate usually originates in the PZ of the prostate (Figure 77.2), so ‘prostatectomy’ for benign enlargement of the gland confers no protection from subsequent carcinoma.

Pathology
Serial sections of prostates obtained at routine necropsy demonstrate prostate carcinoma in 25 per cent of men between 50 and 65 years of age. The incidence in men over 80 years is in the region of 70 per cent (Franks). Most of these neoplasms are tiny and (if life had continued) might have remained latent for years.

The following types of prostate cancer occur:
- microscopic latent cancer found on autopsy or at cystoprostatectomy;
- impalpable tumours found incidentally during TURP (T1a and T1b) or following screening by PSA measurement (T1c);
- early, palpable, localised prostate cancer (T2);
- advanced local prostate cancer (T3 and T4);
- metastatic disease, which may arise from a clinically evident tumour (T2, T3 or T4) or from an apparently benign gland (T0, T1), i.e. occult prostate cancer.

It should be noted that only the last two groups cause symptoms, and such tumours are not curable. Only screening or the treatment of incidentally found tumours can result in cure of the disease. The problem is that many such tumours would never progress during the patient’s lifetime; herein lies the problem with prostate cancer (Summary box 77.6).

Summary box 77.6
Prostate cancer detection
- The incidence has increased, and opportunistic PSA testing has enabled the detection of early-stage disease
- It is not yet clear whether national screening programmes for prostate cancer should be instigated
- Patients should be counselled about the investigations and treatment options available before a PSA test is performed

Screening for prostate cancer
The cancer detection rate using measurement of PSA is between 2 and 4 per cent, and approximately 30 per cent of men with an elevated PSA will have prostate cancer confirmed by biopsy. Unfortunately, 20 per cent of men with clinically significant prostate cancer will have PSA values within the normal range. There is therefore controversy over the usefulness of PSA alone as a screening procedure. One of the two recent prospective screening trials (the other was inconclusive due to contamination) suggests that screening with PSA does prevent death due
to prostate cancer, but that a lot of men must be screened and treated to prevent one death. At present, in Europe, population-based screening is performed only within the confines of clinical trials.

**Histological appearances**

The prostate is a glandular structure consisting of ducts and acini; thus, the histological pattern is one of an adenocarcinoma. The prostatic glands are surrounded by a layer of myoepithelial cells. The first change associated with carcinoma is the loss of the basement membrane, with glands appearing to be confluent. As the cell type becomes less differentiated, more solid sheets of carcinoma cells are seen. A classification of the histological pattern based on the degree of glandular de-differentiation and its relation to stroma has been devised by Gleason. Prostate cancers exhibit heterogeneity within tissue, and so two histological areas of prostate are each scored between 1 and 5. The scores are added to give an overall Gleason score of between 2 and 10; this (and the volume of the cancer) appears to correlate well with the likelihood of spread and the prognosis.

**Local spread**

Locally advanced tumours tend to grow upwards to involve the seminal vesicles, bladder neck and trigone and, later, the tumours tend to spread distally to involve the distal sphincter mechanism. Further upward extension obstructs the lower end of one or both ureters, obstruction of both resulting in anuria. The rectum may become stenosed by tumour infiltrating around it, but direct involvement is rare.

**Spread by the bloodstream**

Spread by the bloodstream occurs particularly to bone; indeed, the prostate is the most common site of origin for skeletal metastases, followed in turn by the breast, the kidney, the bronchus and the thyroid gland. The bones involved most frequently by carcinoma of the prostate are the pelvic bones and the lower lumbar vertebrae. The femoral head, rib cage and skull are other common sites.

**Lymphatic spread**

Lymphatic spread may occur (1) via lymphatic vessels passing to the obturator fossa or along the sides of the rectum to the lymph nodes beside the internal iliac vein and in the hollow of the sacrum and (2) via lymphatics that pass over the seminal vesicles and follow the vas deferens for a short distance to drain into the external iliac lymph nodes. From retroperitoneal lymph nodes, the mediastinal nodes and occasionally the supraclavicular nodes may become implicated.

**Staging using the tumour, node, metastasis (TNM) system (Figure 77.16)**

1 T1a, T1b and T1c. These are incidentally found tumours in a clinically benign gland after histological examination of a prostatectomy specimen. T1a is a tumour involving less than 5 per cent of the resected specimen; these tumours are usually well or moderately well differentiated. T1b is a tumour involving >5 per cent of the resected specimen. T1c tumours are impalpable tumours found following investigation of a raised PSA.

2 T2a disease presents as a suspicious nodule (Figure 77.17) on rectal examination confined within the prostate capsule and involving one lobe. T2b disease involves both lobes.

3 T3 tumour extends through the capsule (T3a, uni- or bilateral extension. T3b, seminal vesical extension).

4 T4 is a tumour that is fixed or invading adjacent structures other than seminal vesicles – rectum or pelvic side wall (Summary box 77.7).

**Summary box 77.7**

**The natural history of prostate cancer**

This depends on the stage and grade of disease:

- T1 and T2
  - The progression rate of well-differentiated T1a prostate cancer is very low: 10–14 per cent after eight years. For moderately differentiated tumours, the rate is about 20 per cent
  - For T1b and T2 tumours, the rate is in excess of 35 per cent

- T3 and T4 (MO)
  - About 50 per cent progress to bony metastases after 3–5 years

- M1
  - The median survival of men with metastatic disease is about three years

**Clinical features**

Only advanced disease gives rise to symptoms, but even advanced disease may be asymptomatic. Symptoms of advanced disease include:

- BOO;
- pelvic pain and haematuria;
- bone pain, malaise, ‘arthritis’, anaemia or pancytopenia;
- renal failure;
- locally advanced disease or even asymptomatic metastases, which may be found incidentally on investigation of other symptoms.

Early prostate cancer is asymptomatic and may be found:

- incidentally following TURP for clinically benign disease (T1);
- as a nodule (T2) on rectal examination (Summary box 77.8).

**Rectal examination**

Rectal examination can detect nodules within the prostate and advanced disease. TRUS may be used to access the local stage and can be combined with a needle core biopsy (Figure 77.18). Irregular induration, characteristically stony hard in part or in the whole of the gland (with obliteration of the median sulcus), suggests carcinoma. Extension beyond the capsule up into the

---

bladder base and vesicles (Figure 77.19 demonstrates normal vesicles) is diagnostic, as is local extension through the capsule (Figure 77.20).

**Prostatic biopsy**

If there is suspicion of prostate cancer, because of local findings, a raised PSA or metastatic disease, then a transrectal biopsy using an automated gun is recommended. Routine local anaesthetic is used to decrease pain. About ten systematic biopsy cores are obtained, as well as biopsy of any suspicious areas. Broad spectrum antibiotic cover is given to all patients to reduce the incidence of sepsis.

If there are associated symptoms of BOO, then either:

- a TURP can be performed, which will provide diagnostic material and symptomatic relief;
- a transrectal biopsy can be carried out. If the diagnosis is positive and there is locally advanced disease, then hormone ablation can provide good symptomatic relief without the need for operation.

**General blood tests**

These are normal in early disease but, in metastatic disease, there may be leuko-erythroblastic anaemia secondary to extensive marrow invasion, or anaemia may be secondary to renal failure. There may be thrombocytopenia and evidence of disseminated intravascular coagulopathy with increased fibrinogen degradation products (FDPs).

**Liver function tests**

These will be abnormal if there is extensive metastatic invasion of the liver. The alkaline phosphatase may be raised from either hepatic involvement or secondaries in the bone. These can be distinguished by measurement of isoenzymes or gamma-glutamyltransferase.

**Prostate-specific antigen**

This is discussed earlier in this chapter. It is good at following the course of advanced disease. It is lacking in sensitivity and specificity in the diagnosis of early localised prostate cancer. Nevertheless, the finding of a PSA >10 nmol/mL is suggestive of cancer and >35 ng/mL is almost diagnostic of advanced prostate cancer. A decrease in PSA to the normal range following hormonal ablation is a good prognostic sign.

**Acid phosphatase**

Acid phosphatase has been superseded by measurement of PSA.
Radiological examination

X-rays of the chest may reveal metastases in either the lung fields or the ribs. An abdominal x-ray may show the characteristic sclerotic metastases in lumbar vertebrae and pelvic bones (Figure 77.21). The bone appears dense and coarse, and it is sometimes difficult to distinguish the change from that in Paget's disease of bone. Nevertheless, osteolytic metastases are very common in prostate cancer and may coexist with sclerotic ones. Information about the upper urinary tracts can be obtained by excretion urography or ultrasound.

Cross-sectional imaging with magnetic resonance imaging and TRUS

Magnetic resonance imaging (MRI) with a high tesla magnet (1.5–3 T) is the most accurate method of staging local disease.

Transrectal ultrasound scanning can also be used. Locally extensive disease (T2) can be diagnosed with increased sensitivity by TRUS (Figure 77.17) compared with rectal examination, but many tumours will still be missed. This problem remains a real one in screening for early prostate cancer; in comparison with breast cancer, with mammography detecting 70–80 per cent of tumours, TRUS plus rectal examination and measurement of PSA will detect only 30–50 per cent of cancers that are known to be present on autopsy studies (although it may detect the larger, more significant cancers).

Bone scan

Once the diagnosis has been established, it would be normal to perform a bone scan as part of the staging procedure if the PSA were >10 nmol/mL or if the biopsy showed high-grade cancer. If the PSA is <10 nmol/mL, then a bone scan would be performed only on clinical indications. The bone scan is performed by the injection of technetium-99m, which is then monitored using a gamma camera. It is more sensitive in the diagnosis of metastases (Figure 77.22) than a skeletal survey, but false positives occur in areas of arthritis, osteomyelitis or a healing fracture.

Lymphangiography

This is no longer carried out. If accurate information is required, then pelvic lymphadenectomy can be performed by means of laparoscopic surgery.

Bone marrow aspiration

Sometimes, examination of the bone marrow will reveal the presence of metastatic carcinoma cells.

Treatment of carcinoma of the prostate

Early disease

Curative treatment can only be offered to patients with early disease (T1a, T1b, T1c and T2). T1a disease found incidentally at TURP is by definition low volume and usually well differentiated. This stage can often be managed by active surveillance, with three- to six-monthly digital rectal examination (DRE)
Carcinoma of the prostate

and PSA measurement, considering treatment if there is evidence of disease progression. The options available for T1b, T1c and T2 disease need to take into account patient age, performance status and lifestyle preferences. The treatment of patients with advanced disease (T3, T4 or any M0) is only palliative (Summary box 77.9).

**Summary box 77.9**

**Treatment and stage**

- Treatment options for prostate cancer depend on stage of disease, life expectancy of the patient and patient preference.
- PSA, DRE and biopsy Gleason grade are used to predict pathological stage.
- Localised cancer can be treated by radical prostatectomy, radiation therapy and active monitoring.
- Treatment of advanced disease is palliative, and hormone ablation remains the first-line therapy.

**Radical prostatectomy**

Radical prostatectomy is only suitable for localised disease (T1 and T2) and should be carried out only in men with a life expectancy of >10 years. Exclusion of metastases would require a negative bone scan, chest x-ray and a serum PSA <20 nmol/mL. It is a procedure that should be performed only by experienced surgeons when there is a high chance of cure. It results in a high incidence of impotence, but a low incidence of severe stress incontinence (<2 per cent), which may require the fitting of an artificial urinary sphincter. It involves removal of the prostate down to the distal sphincter mechanism in addition to the seminal vesicles (Figure 77.23). The bladder neck is reconstituted and anastomosed to the urethra. Recent modifications to this operation by Professor Patrick Walsh of the Johns Hopkins Hospital in Baltimore have led to the realisation that careful dissection in early-stage disease can lead to preservation of the neurovascular bundles that lie behind the prostate. This modification has led to the preservation of erectile function in about 60–70 per cent of cases. Recently, laparoscopic approaches to radical prostatectomy, sometimes supported by robotic techniques, have been introduced.

**Radical radiotherapy for early prostate cancer**

External beam radiotherapy (EBRT) can be administered in fields that conform to the contours of the prostate, thereby limiting exposure of adjacent tissues. Survival rates following the treatment of T1 and low-volume T2 disease are not greatly different from those following radical prostatectomy, although histological evidence of persistent tumour is found within the prostate in about 30 per cent of treated patients. The treatment of T3 disease which has spread through the capsule of the gland is controversial. Surgery, radiotherapy, androgen ablation or combinations of the above are used. The treatment requires the patient to attend hospital on a daily basis for between 4 and 6 weeks. Some local complications are inevitable, namely irritation of the bladder with urinary frequency, urgency and sometimes urge incontinence and similar problems affecting the rectum with diarrhea and, occasionally, late radiation proctitis. Development of erectile dysfunction occurs less frequently than following radical prostatectomy, but is present in up to 30 per cent of cases.

**Brachytherapy**

Under transrectal ultrasound guidance, radioactive seeds are permanently implanted into the prostate. A computer program converts accurate ultrasound measurements of the prostate gland to construct a plan of the gland. Under anaesthesia, the patient is placed in the lithotomy position and, according to the template plan, seeds are placed through transperineal needles.

![Figure 77.22](image1) Bone scan showing multiple hot-spots suggestive of metastatic disease in a man with prostate cancer.

**Figure 77.23** Radical prostatectomy specimen for a T2a prostate cancer. Preoperative PSA was 6 ng/L; postoperative levels remained undetectable at eight years. The patient is fully continent.

---

Patrick C Walsh, Professor of Urology, Johns Hopkins Hospital, Baltimore, MD, USA. Recipient of 2007 National Physician of the Year Clinical Excellence Award.
The radioisotopes commonly used are iodine-125 and palladium-103. These isotopes deliver an intense, confined radiation dose, which falls off rapidly to spare the surrounding structures. Brachytherapy is gaining widespread acceptance for the treatment of lower grade low-volume T1 disease. A major factor is the reduced perioperative complications and generally low morbidity. Long-term cancer survival results from institutions specialising in the procedure are encouraging.

**Advanced disease**

There is still debate about the timing of androgen ablation treatment in patients with locally advanced or metastatic disease without symptoms. The options are androgen deprivation at diagnosis or careful review, reserving active treatment for the later development of symptoms. Patients with poorly differentiated disease are at risk of a catastrophic event such as spinal cord compression; in these patients, early androgen ablation can prolong the time to complications. Also, patients with local or general symptoms should be offered androgen deprivation.

**Orchidectomy**

Orchidectomy is performed to carry out androgen ablation in the treatment of locally advanced (T3 or T4) disease or of metastatic disease. In 1941, prostate cancer was shown to be responsive to such treatment by Charles Huggins, the only urologist to win a Nobel Prize. Bilateral orchidectomy, whether total or subcapsular, will eliminate the major source of testosterone production.

**Medical castration**

Medical forms of androgen ablation have been available since the discovery of stilbestrol. The other commonly available treatment to reduce testosterone levels to the castrate range is LHRH agonists. These agents initially stimulate hypothalamic LHRH receptors but, because of their constant presence (rather than the normal diurnal rhythm), they then downregulate them, resulting in cessation of pituitary LH production and, hence, a decrease in testosterone production. In the first 10 days or so, serum testosterone levels may increase, and it is wise to give flutamide, bicalutamide or cyproterone acetate for this period. LHRH agonists may be given by monthly or three-monthly depot injection.

Other treatments that block the androgen receptor have become available recently. Cyproterone acetate also has some progestogenic effect, while flutamide and bicalutamide are pure anti-androgens. In general, oral anti-androgen monotherapy has not been shown to be as good as LHRH agonists or orchidectomy. New types of drugs affecting the LHRH–androgen axis, such as LHRH antagonists, superpotent androgen receptor antagonists and drugs inhibiting androgen biosynthesis, are in clinical trials. The role of these drugs is yet to be established.

**Complete androgen blockade**

Complete androgen blockade has been advocated as being likely to result in increased life expectancy and an increased time to progression in a fitter subgroup of men with advanced prostate cancer. The concept is that of abolishing the testicular secretion of testosterone by means of orchidectomy or the use of LHRH therapy and then inhibiting the effects of adrenal androgenic steroids by means of androgen receptor blockade with flutamide, bicalutamide or the use of cyproterone acetate. Recent overviews of randomised trials do not confirm earlier reports of effectiveness.

**General radiotherapy**

Radiotherapy for symptomatic metastases is an excellent form of palliative treatment, often producing dramatic pain relief in men with hormone-relapsed prostate cancer that can last up to six months. When multiple sites are involved, intravenous radiopharmaceuticals such as strontium-89 can be employed. Strontium is a bone-seeking isotope that delivers effective radiotherapy to metastatic areas. It appears to be as effective as hemibody irradiation in the treatment of men with metastatic hormone-relapsed disease; however, the duration of response has been disappointing.

**Chemotherapy**

Cytotoxic agents in the treatment of these men have proved disappointing, but whether this is because the tumour is inherently insensitive or because these elderly men will not tolerate effective doses is uncertain. Recent trials of docetaxel have shown improvements in survival, but only by a few months.

**Summary of treatment**

1. **Incidentally diagnosed T1a and T1b disease.** For men in their 70s, conservative treatment would usually be the correct approach. Radical surgical treatment might be considered in the younger (<70 years) man with this form of the disease, although even in this group, some men will elect to pursue a conservative course when counselled about risks versus benefits.

2. **Localised T1c and T2 disease.** In younger, fitter men (<70 years), this may be treated by radical prostatectomy or radical radiotherapy. Active monitoring remains an option, particularly for more elderly patients with low-grade disease. In the elderly patient with outflow obstruction, transurethral resection with or without hormone therapy is indicated. The benefit of radical treatment over a conservative approach is likely to be about 25 per cent, given that progression to metastatic disease is of this order of magnitude after 10 years.

3. **Locally advanced T3 and T4 disease.** These patients are at significant risk of disease progression. Early androgen ablation is favoured if close follow up is not possible. For the sexually active, a careful conservative approach with the adoption of androgen ablation when symptoms arise is reasonable. Androgen ablation coupled with radiotherapy is standard treatment for younger men with T3 disease.

4. **Metastatic disease.** Once metastases have developed, the outlook is poor. For patients with symptoms, there is no dilemma; androgen ablation will provide symptomatic relief in over two-thirds of patients. For patients with asymptomatic metastases, the timing of treatment is less clear. Systemic chemotherapy with docetaxel should be considered in younger, fitter men.

**PROSTATITIS**

In both acute and chronic prostatitis, the seminal vesicles and posterior urethra are usually also involved.
Acute prostatitis

Aetiology

Acute prostatitis is common, but underdiagnosed. The usual organism responsible is Escherichia coli, but Staphylococcus aureus, Streptococcus albus, Neisseria gonorrhoeae or Chlamydia may be responsible. The infection may be haematogenous from a distant focus, or it may be secondary to acute urinary infection.

Clinical features

General manifestations overshadow the local: the patient feels ill, shivers, may have a rigor, has ‘aches’ all over, especially in the back, and may easily be diagnosed as having influenza. The temperature may be up to 39°C. Pain on micturition is usual, but not invariable. The urine contains threads in the initial voided sample, which should be cultured. Perineal heaviness, rectal irritation and pain on defaecation can occur; a urethral discharge is rare. Frequency occurs when the infection involves the bladder. Rectal examination reveals a tender prostate; one lobe may be swollen more than the other, and the seminal vesicles may be involved. A frankly fluctuant abscess is uncommon.

Treatment

Treatment must be vigorous and prolonged or the infection will not be eradicated and recurrent attacks may ensue. Spread of infection to the epididymides and tests may occur. Prolonged treatment with an antibiotic that penetrates the prostate well is indicated (trimethoprim or ciprofloxacin).

Prostatic abscess

In addition to the foregoing symptoms and signs, the advent of a prostatic abscess is heralded by the temperature rising steeply with rigors. Antibiotics disguise these features. Severe, unremitting perineal and rectal pain with occasional tenesmus often cause the condition to be confused with an anorectal abscess. Nevertheless, if a rectal examination is performed, the prostate will be felt to be enlarged, hot, extremely tender and perhaps fluctuant. Retention of urine is likely to occur and, in such men, suprapubic catheterisation is best.

Treatment

The abscess should be drained without delay:
- The abscess can be drained by perurethral resection – unroofing the whole cavity.
- The perineal route is rarely indicated unless there is marked periprostatic spread.

Chronic prostatitis

Many urologists find the diagnosis of chronic prostatitis and ‘prostatodynia’ very difficult, for many men present with perigenital pain, testicular pain, prostatic pain exacerbated by sexual intercourse or pain that apparently renders sexual intercourse out of the question. Psychosexual dysfunction in such patients may be the underlying problem. The diagnosis of chronic prostatitis has to be based on:
- Persistent threads in voided urine;
- Prostatic massage showing pus cells with or without bacteria in the absence of urinary infection.

Aetiology

This is thought to be the sequel of inadequately treated acute prostatitis. While pus is present in the prostatic secretion, the responsible organism is often difficult to find. Other organisms such as Chlamydia species may be responsible for chronic abacterial prostatitis.

Clinical features

The clinical features are extremely varied. Only men with symptoms of posterior urethritis, prostatic pain and perigenital pain accompanied by intermittent fever and pus cells or bacteria in the post-prostatic massage specimen should be diagnosed as having chronic prostatitis.

Diagnosis

The three-glass urine test is valuable. If the first glass with the initial voided sample shows urine containing prostatic threads, prostatitis is present.

Rectal examination of the prostate may be normal or may show a soft, boggy and tender prostate.

Examination of the prostatic fluid obtained by prostatic massage should show pus cells and bacteria.

Urethroscopy may reveal inflammation of the prostatic urethra, and pus may be seen exuding from the prostatic ducts. The verumontanum is likely to be enlarged and oedematous. In many men with the symptoms described above, all investigations are normal.

Treatment

Antibiotic therapy should be administered only in accordance with bacteriological sensitivity tests. Trimethoprim penetrates well into the prostate. If Trichomonas or anaerobes are the responsible agent, a rapid response is obtained from administration of flagyl (metronidazole, 200 mg tds for 7 days to both partners). If Chlamydia is suspected, doxycycline is the antibiotic treatment of choice. It is uncertain whether prostatic massage helps in eradicating the infection.

Prostatodynia

This diagnosis is made by the presence of perigenital pain in the absence of any objective evidence of prostatic inflammation. Whether the syndrome has any relationship with the prostate is unclear.

TUBERCULOSIS OF THE PROSTATE AND SEMINAL VESICLES

Tuberculosis of the prostate and seminal vesicles is rare and associated with renal tuberculosis. In 30 per cent of cases, there is a history of pulmonary tuberculosis within five years of the onset of genital tuberculosis.

Tuberculosis of one or both seminal vesicles may be found when examining a patient with chronic tuberculous epididymitis, no symptoms being referable to the internal genitalia. On rectal examination, the affected vesicle is found to be nodular.

When the prostate is involved, rectal examination reveals nodules in one or both lateral lobes. Patients with tuberculous prostatitis usually present with the following:
- Urethral discharge;
painful, sometimes blood-stained, ejaculation;
• mild ache in the perineum;
• infertility;
• dysuria;
• abscess formation.

**Special forms of investigation**

X-ray sometimes displays areas of calcification in the prostate and/or the seminal vesicles.

Bacteriological examination of the seminal fluid yields positive cultures for tubercle bacilli.

**Treatment**

The general treatment is that for tuberculosis. If a prostatic abscess forms, it should be drained transurethrally.

---

**SEMINAL VESICLES**

**Acute seminal vesiculitis**

Acute seminal vesiculitis occurs in association with prostatitis. Prior to the antibiotic treatment of gonorrhoea, gonococcal vesiculitis was common.

**Chronic seminal vesiculitis**

Chronic seminal vesiculitis usually presents with haematospermia and pain on intercourse. TRUS demonstrates the features of distension and thickening and the presence of turbid fluid. The treatment is the same as for chronic prostatitis.

**Tuberculous seminal vesiculitis**

The clinical features and treatment have been discussed above.

**Diverticulum of the seminal vesicle**

Diverticulum of the seminal vesicle occurs occasionally. In such cases, the kidney of that side is absent, and the diverticulum represents an abortive ureteric bud. It is a cause of persistent infection.

**Cyst of the seminal vesicle**

A cyst of the seminal vesicle is uncommon and rarely requires treatment. It may be removed by dissection through an incision similar to that for perineal prostatectomy, if it is large or giving rise to symptoms.

THE MALE URETHRA

Anatomy
The male urethra is a tubular structure extending from the bladder neck to the external urinary meatus at the tip of the glans penis. It has four components which are named (from proximal to distal), the prostatic, membranous, bulbar and penile urethra. The prostatic urethra extends from the bladder neck to the verumontanum and is compressed on either side by the lateral lobes of the prostate, giving it a slit-like configuration. The verumontanum is a small hillock of tissue indented at its crown by a pit called the utriculus masculinus which marks the proximal extent of the external urethral sphincter and is an important landmark for urologists performing transurethral resection of the prostate. The membranous urethra lies just distal to the verumontanum and is located where the urethra penetrates the pelvic floor and it is the usual site of urethral rupture at the time of a pelvic fracture. It is the primary location of continence as a consequence of the surrounding pelvic floor musculature and external urethral sphincter. The bulbar urethra extends from the membranous urethra to the penoscrotal junction and is anteriorly located within the corpus spongiosum. The penile urethra is normally flattened anteroposteriorly, but distends when filled with fluid. The penile urethra becomes dilated within the glans penis where it is named the ‘navicular fossa’.

The external urethral sphincter is composed of circular striated muscle within the urethral wall. The bladder neck contributes to maintenance of continence in the man, although its main role is as a genital sphincter that closes at the time of ejaculation.

Congenital abnormalities
Posterior urethral valves
Posterior urethral valves occur in around one in 5000–8000 live male births. The valves are membranes which typically lie just distal to the verumontanum and cause obstruction to the urethra of boys. They are flap valves and so although they are obstructive to antegrade urinary flow, a urethral catheter can be passed retrogradely without any difficulty. The diagnosis is commonly made antenatally with ultrasound which demonstrates bilateral hydronephrosis above a distended bladder. If the diagnosis is not made antenatally, then patients typically present with urinary infection in the neonatal period or with uraemia and renal failure. Rarely the valves are incomplete and the patient is symptom free until adolescence or adulthood when again urinary infection or renal impairment can supervene.

Diagnosis
Posterior urethral valves need to be detected and treated as early as possible to minimise the degree of renal failure. The valves can be difficult to see on urethroscopy because the flow of irrigant sweeps them into the open position. If the bladder is filled with contrast medium, the dilatation of the urethra above the valves can be demonstrated on a voiding cystogram (Figure 78.1). The bladder is hypertrophied and often shows diverticula. Typically, there is vesicoureteric reflux into dilated upper tracts (Summary box 78.1).

Summary box 78.1
Posterior urethral valves
- Posterior urethral valves are congenital membranes that cause obstruction to the urinary tract in baby boys
- Antenatal ultrasound typically shows urinary tract dilatation
- If not recognised antenatally, they may cause recurrent urinary infection, urinary retention and uraemia
- Treatment is valve destruction accompanied by treatment of urinary infection and renal impairment
Treatment

Initial treatment is by catheterisation to relieve the back pressure and to allow the effects of renal failure to improve. Definitive treatment is by endoscopic destruction of the valves with continuing supportive treatment of the dilated urinary tract, the recurrent urinary infections and the uraemia (Summary box 78.1).

Hypospadias

Hypospadias occurs in around one in 200–300 male live births and is the most common congenital abnormality of the urethra (see also Chapter 8). There are three characteristic features. Firstly the external meatus opens on the underside of the penis or the perineum, secondly the ventral aspect of the prepuce is poorly developed ('hooded prepuce') and thirdly there is a ventral deformity of the erect penis (chordee).

Hypospadias is classified according to the position of the meatus (Figure 78.2).

- **Glanular hypospadias.** The ectopic meatus is placed on the glans penis, but proximal to the normal site of the external meatus which is marked by a blind pit. Occasionally the two are connected by a channel.
- **Coronal hypospadias.** The meatus is placed at the junction of the underside of the glans and the body of the penis.
- **Penile and penoscrotal hypospadias.** The meatus is on the underside of the penile shaft.
- **Perineal hypospadias.** This is the rarest and most severe abnormality. The scrotum is bifid and the urethra opens between its two halves. There may be testicular maldescent, which may make it difficult to determine the sex of the child.

The more severe varieties of hypospadias represent an absence of the urethra and corpus spongiosum distal to the ectopic opening. The absent structures are represented by a fibrous cord, which deforms the penis in a downward direction (chordee).

Treatment

Hypospadias does not cause either obstruction or urinary tract infection. Surgery is indicated to improve sexual function, to correct problems with the urinary stream and for cosmetic reasons. A variety of plastic surgical procedures have been described to correct the chordee and to re-site the urethral opening. Some techniques utilise the foreskin and therefore circumcision should be avoided before the hypospadias has been repaired. Operations for hypospadias are best performed by a paediatric urologist and are typically undertaken before the age of one year (Summary box 78.2).

**Summary box 78.2**

**Hypospadias**

- Hypospadias is characterised by the combination of a ventrally placed urethral meatus, a hooded foreskin and chordee.
- Avoid circumcision as the prepuce may be used in procedures to correct the abnormality.
- Surgical treatment should be undertaken by a paediatric urologist.

Epispadias

Epispadias is very rare. In penile epispadias, the urethral opening is on the dorsum of the penis and is associated with an upward curvature of the penis (Figure 78.3). Epispadias often coexists with bladder extrophy and other severe developmental defects.

Urethral diverticulum

This is usually congenital and represents a partial duplication of the urethra. Acquired cases are uncommon but are sometimes seen as a result of increased intraurethral pressure behind a stricture. Others are caused by the longstanding presence of a foreign body such as a stone or calculus in the urethra.

Typically, patients present in adult life with a history of post-micturition dribbling and diagnosis is made at cystoscopy (Figure 78.4) or via a urethrogram. Treatment is often unnecessary, but they can be treated endoscopically by incising the flap of urethral
The male urethra

mucosa between the two lumens, or in severe cases by excision of the diverticulum.

**Injuries to the male urethra**

**Rupture of the bulbar urethra**

There is a history of a blow to the perineum, usually due to a fall astride injury. The bulbar urethra is crushed upwards onto the pubic bone, typically with significant bruising. In the days of sailing ships, the common cause was falling astride a spar and the modern equivalent is seen among workers losing their footing on scaffolding. Cycling accidents, loose manhole covers and gymnasium accidents astride the beam account for a number of cases. Almost certainly King William I of England died in 1087 following a ruptured bulbar urethra that he sustained when falling off his horse. It is thought that he ruptured the urethra on the saddle’s pommel and he subsequently developed urinary retention and sepsis secondary to infection of the haematoma and he died some days after the accident.

Extravasation of urine is common and the extravasated urine is confined in front of the midperineal point by the attachment of Colles’ fascia to the triangular ligament and by the attachment of Scarpa’s fascia just below the inguinal ligament. The external spermatic fascia stops it getting into the inguinal canals. Extravasated urine collects in the scrotum and penis and beneath the deep layer of superficial fascia in the abdominal wall.

**Clinical features**

The signs of a ruptured bulbar urethra are perineal bruising and haematoma, typically with a butterfly distribution. There is usually bleeding from the urethral meatus and retention of urine is also typically present.

**Management**

If the diagnosis is suspected, the patient should be treated with appropriate analgesia and antibiotics should be administered. He should be discouraged from passing urine. A full bladder should be drained with a catheter placed by percutaneous suprapubic puncture (Figure 78.5). This reduces urinary extravasation and allows investigations to establish the extent of the urethral injury. If the patient has passed urine when first seen and there is no extravasation, the rupture, if any, is partial and a suprapubic catheter is not usually needed. Diagnosis is made by urethrography using water soluble contrast.

If there is significant extravasation, then the perineal collection should be drained.

If the urethral tear is complete, the suprapubic catheter should remain in situ while the bruising and extravasation settle down. A stricture will typically develop at the site of the injury. The optimal treatment is delayed anastomotic urethroplasty after the swelling and bruising have settled down (typically 8–12 weeks later), with excision of the traumatised section and spatulated end-to-end reanastomosis of the urethra (Summary box 78.3).

**Summary box 78.3**

**Bulbar urethral injury**

- Suspect urethral injury after blunt perineal trauma when the man cannot void, when there is perineal bruising and when there is blood at the urethral meatus
- The safest initial management is to insert a suprapubic catheter
- Beware of urinary extravasation and sepsis in the perineal haematoma
- Delayed urethroplasty is the preferred definitive management of complete disruptions

**Rupture of the membranous urethra**

Rupture of the membranous urethra typically occurs in association with a fractured pelvis and may be associated with an extraperitoneal rupture of the bladder. When the pelvic fractures, the membranous urethra is ruptured as it passes through the bony ring of the pelvis. The urethra is elastic at this point, and if the fracture results in only a minor displacement, then the tear may only be partial, but more typically the rupture is complete, such that the two ends are completely displaced, with the develop-
ment of a significant interposing haematoma. About 5 per cent of cases of fractured pelvis have an associated urethral injury and such injuries are almost universally seen in men.

**Clinical features**

The most common causes of pelvic fracture are road traffic accidents, severe crush injuries and falls. Typically there are multiple associated injuries that may be immediately life threatening and the overriding priority is to keep the patient alive by appropriate resuscitation. Under these circumstances, the management of the other injuries takes precedence.

The clinical features include urinary retention, blood at the urethral meatus and a high riding prostate on digital rectal examination. If the diagnosis is suspected, a urethrogram performed with water soluble contrast media is confirmatory (Figure 78.6).

A suprapubic catheter should be inserted as soon as practicable. The distended bladder may be palpable making suprapubic catheterisation straightforward, but often the bruising and swelling associated with the fracture makes this difficult and ultrasound guidance is required. In the presence of a coexistent extraperitoneal bladder injury, no bladder will be apparent on ultrasound examination, and surgical exploration, bladder repair, suprapubic catheter placement and drainage of the retropubic space are needed.

**Complications**

**Urethral disruption injury**

The two ends of the urethra, having been torn apart, become separated by a haematoma. With time, this haematoma resolves and is replaced by fibrosis. This pelvic fracture urethral disruption injury is technically not a stricture of the urethra but is often erroneously described as being one. The conventional management of such an injury is delayed surgical reconstruction with excision of the scar tissue and end to end anastomosis. This surgery should be delayed until the patient has recovered from any other injuries and is usually undertaken 3–6 months later. It is a highly challenging technical procedure and should be undertaken only in specialist centres. Some surgeons continue to undertake early attempts to realign the urethral ends endo-
The male urethra

The male urethra

The male urethra is approximately 25 cm long and is divided into three sections: the prostatic, membranous, and anterior urethra. The prostatic urethra is located within the prostate gland and is approximately 3 cm long. The membranous urethra is 2 cm long and is located within the urogenital diaphragm. The anterior urethra is the longest section, approximately 14 cm long, and is located within the perineum and penis.

Urinary incontinence

Urinary incontinence can occur due to damage to the external urethral sphincter, which is a voluntary muscle that helps to control urination. Incontinence can be acute or chronic and can be caused by various factors such as bladder neck obstruction, neurological disorders, and neurogenic bladder.

Erectile dysfunction

Erectile dysfunction, also known as impotence, is a common condition that affects a significant number of men. It is characterized by the inability to achieve or maintain an erection sufficient for sexual intercourse.

Inflammation of the urethra

Inflammatory conditions of the urethra include:

- Meatal ulcer
- Urethritis
- Gonococcal urethritis
- Non-specific urethritis
- Reiter's disease
- Peri-urethral abscess.

Ameatal ulcer is an uncommon complication of neonatal circumcision and may develop up to two years after the circumcision. Lack of protection by the prepuce seems to be the primary cause, with friction from clothing and ammoniacal dermatitis also being contributory factors. Devascularisation caused by ligation of the frenular artery may also possibly play a part. The ulcer forms a scab that blocks the meatus and the child can pass urine only by bursting the scab. This hurts, so the boy screams; a tiny amount of blood may be passed as well. The process causes fibrosis, which can result in an acquired pinhole meatus. Local measures to soften the scab and alkalinise the urine are often curative although a few do need meatotomy.

Gonorrhoeal urethritis

Gonorrhea is a sexually transmitted disease caused by Neisseria gonorrhoeae (gonococcus), a Gram-negative kidney-shaped diplococcus that infects the anterior urethra in men, the urethra and cervix in women and the oropharynx, rectum and anal canal in both sexes, but especially men. It is transmitted by unprotected sexual intercourse.

Most men have symptoms typical of urethral discomfort and urethral discharge. There is often scalding dysuria. In women it is often asymptomatic. Symptoms, which are present in 50 per cent or less, usually consist of a mild dysuria or slight urethral discharge, which can go unnoticed by the patient. Cervicitis can occur with about 10 per cent suffering from pelvic inflammatory disease (salpingitis), which, if bilateral, may lead to infertility. A mother may transmit gonorrhea to her newborn during childbirth with the risk that blindness of the child can result. In addition, in both men and women exposed orally or anally, gonococcal infections can cause a predominantly asymptomatic pharyngitis or proctitis.

Extravasation of urine

Extravasation of urine can occur with extraperitoneal rupture of the bladder, pelvic fracture urethral disruption or in the rare cases where the level of the disruption is the prostatic urethra. Urine extravasates in the layers of the pelvic fascia and the retroperitoneal tissues. Treatment is by suprapubic cystostomy. In rare cases where the extravasation persists despite the suprapubic tube, then drainage of the retropubic space and the definitive repair of the urethral, prostatic or bladder rupture is required (Summary box 78.4).

Summary box 78.4

Pelvic fracture urethral disruption injury

- Suspect the diagnosis in cases of pelvic fracture, when the patient has not voided and when there is blood at the urethral meatus
- A water soluble urethrogram confirms the diagnosis
- Initial management is insertion of a suprapubic catheter
- Surgical exploration is needed if there is coexistent rupture of the bladder
- Delayed anastomotic urethroplasty is the preferred definitive management

Inflammation of the urethra

Inflammatory conditions of the urethra include:

- Meatal ulcer
- Urethritis
- Gonococcal urethritis
- Non-specific urethritis
- Reiter's disease
- Peri-urethral abscess.
Investigations
Traditionally the diagnosis was made by identification of pus and gonococci in a Gram-stained urethral smear with subsequent culture. However, more recently PCR-based techniques, which are more sensitive, are the norm.

Complications
Complications are prevented by effective early treatment. In men, complications include posterior urethritis, prostatitis (acute or chronic), acute epididymo-orchitis, periurethral abscess and urethral stricture. Gonococcal arthritis, iridocyclitis, septicemia and endocarditis are unusual.

Treatment
Treatment is with antibiotics, with ceftriaxone currently the treatment of choice as a consequence of the increasing prevalence of antibiotic resistance to more traditional antibiotics such as ciprofloxacin or penicillin. Contact tracing is important in controlling the spread of the disease and management is usually by a genitourinary physician.

Non-specific urethritis (synonym: non-gonococcal urethritis)
Non-specific urethritis (NSU) is a sexually transmitted infection that in around 40 per cent of cases is due to Chlamydia trachomatis with other cases being caused by Ureaplasma urealytica or Mycoplasma genitalium. The causative agent in up to 50 per cent of cases is unknown.

Clinical features
In men, dysuria and a white mucopurulent urethral discharge appear up to 6 weeks after sexual intercourse. The urine appears to be clear but may contain ‘threads’ or pus cells. Epididymitis is common and urethral stricture can result. In women, the condition is usually asymptomatic although it can present as vaginal discharge or as a form of urethral trigonitis. It may result in cervicitis or pelvic inflammatory disease.

Treatment
Exclusion of gonorrhoeal infection is important. Chlamydial infection is diagnosed by PCR techniques on a urethral swab or a urine sample. Treatment with oxytetracycline or doxycycline is usually effective although relapse is common, especially in men, in whom the prostate may act as a reservoir of infection. Azithromycin is an alternative treatment taken as a single oral dose. It is important to treat both partners as reinfection is probable if this is not done.

Reiter’s disease (synonym: sexually acquired reactive arthritis)
Reiter’s disease is an autoimmune disease characterised by the triad of urethritis or diarrhoea, conjunctivitis and polyarthritis. Common triggers include Chlamydial urethritis, less commonly gonococcal urethritis and diarrhoea secondary to Salmonella, Shigella or Campylobacter. It is an HLA-B27 associated condition. The conjunctivitis (present in around 50 per cent) and arthritis typically occur 1–3 weeks after the primary infection. Diagnosis is made on clinical grounds and treatment is largely symptomatic, although antibiotic treatment of the precipitating infection is important. The urethritis and conjunctivitis frequently subside after a few weeks but the arthritis may persist for months. Severe anterior uveitis and frequently recurrent attacks suggest a poor outlook.

Periurethral abscess
Periurethral abscesses can be penile, bulbar or chronic.

Penile periurethral abscess
A penile periurethral abscess arises as an acute gonococcal infection of one of the glands of Littre. The tender induration felt on the underside of the penis points and discharges externally, often leaving a fistula. An anterior urethrotomy will encourage the abscess to burst into the urethra. When the abscess lies behind a stricture, it should be opened externally.

Bulbar periurethral abscess
A bulbar periurethral abscess is a spreading cellulitis caused by infection with streptococci and anaerobic organisms, possibly associated with a stricture. Extravasation of urine is not unusual. There is perineal pain with pyrexia, rigors and tachycardia. Tenderness and swelling rapidly spread from the perineum to the penis and the anterior abdominal wall. Antibiotics are essential. Collections of pus should be drained and the urethra should be defunctioned by a suprapubic urinary catheter.

Chronic periurethral abscess
A chronic periurethral abscess sometimes results from a longstanding urethral stricture (Figure 78.7). The multiple loculi of pus should be drained and the stricture treated. Urethral fistula occurs either spontaneously or as a result of incision of the abscess.
Urethral stricture

Causes

The common causes of urethral stricture are:

- Inflammatory
  - Secondary to urethritis
  - Secondary to balanitis xerotica obliterans
- Traumatic
  - Bulbar urethral injury
  - Pelvic fracture urethral disruption injury
- Iatrogenic
  - Secondary to urethral instrumentation
  - Secondary to urethral catheterisation
  - Secondary to transurethral prostatectomy
  - Secondary to radical prostatectomy
- Idiopathic.

Pathophysiology

Post-inflammatory strictures are less common since the introduction of effective antibiotic treatment of gonorrhoea. The stricture is most commonly seen in the bulbar urethra but submeatal strictures also occur. There is infection in the periurethral glands which persists after inadequately treated gonorrhoea. The infection spreads to cause a periurethritis, which heals by fibrosis. Most strictures appear within one year of infection but may not cause difficulty in micturition for some time later.

Balanitis xerotica obliterans is a rare condition characterised by fibrosis of the foreskin resulting in phimosis. In around 10 per cent of cases, the glans penis is also affected causing meatal stenosis and, in a proportion of these cases, there is also fibrosis and strictureting of the penile urethra. The cause of the condition is unknown, but the strictures produced are typically long and difficult to treat.

Post-traumatic strictures have been discussed previously.

Post-instrumentation strictures follow endoscopy or catheterisation and may affect any part of the urethra. Some surgeons recommend prophylactic dilatation or urethrotomy before transurethral prostatectomy in order to try to avoid this complication. Some cases of stricture seem to be due to sensitivity to chemicals from a catheter, but most are the result of a combination of trauma, infection and pressure necrosis.

Bladder neck stenosis can occur following transurethral resection of the prostate (TURP) and following radical prostatectomy for the treatment of prostate cancer. If it cannot be managed by dilatation, bladder neck stenosis should be treated by transurethral incision and resection of the stricture, although in the man who has undergone radical prostatectomy, this will result in urinary incontinence.

Clinical features

Symptoms are usually hesitancy of micturition, straining to void and a poor urinary stream. The relative youthfulness of the patient often rules out prostatic enlargement, which characteristically occurs after the age of 50. As the stream becomes narrower, micturition is prolonged and is followed by post-micturition dribbling as a result of urine trickling from the dilated urethra proximal to the stricture. Urinary frequency by day and night is common and is due to incomplete bladder emptying, coexistent detrusor overactivity or urinary infection. The urinary flow rate is typically prolonged and plateau shaped (Figure 78.8).

A well-established stricture may be palpable as scarring along the line of the urethra. If the stricture is tight enough, the patient will go into acute retention, although this is rare. If this happens there is a danger that clumsy attempts to pass a urethral catheter will result in a false passage. If a patient has gone into retention because of a urethral stricture, its lumen will be too narrow to pass even a tiny catheter and suprapubic catheterisation is required.

Urethroscopy allows the stricture to be viewed as a circumferential scar (Figure 78.9). Openings of false passages commemorate previous misguided attempts to pass a urethral catheter.

Urethrogram using a water-soluble contrast medium will show the extent and severity of the stricture (Figures 78.10 and 78.11).
Complications
The most common complication of a urethral stricture is urinary tract infection, which usually responds to antibiotic treatment although there is a tendency for them to recur as a consequence of the increased residual urines within the bladder. Any of the complications of bladder outflow obstruction can occur, including bladder calculi and upper tract dilatation with renal impairment, although the latter is rare. Similarly, retention of urine is also rare, and should be treated by suprapubic catheterisation. Rare complications include urethral diverticulum and paraurethral abscess (Summary box 78.5).

Summary box 78.5

Diagnosis of urethral stricture
- Suspect the diagnosis of urethral stricture in a young man with poor urinary stream
- Diagnosis is made either by visualisation (uroscopy) or radiologically (by urethrography)
- Urinary infection should be excluded

Treatment
The management of urethral strictures has changed considerably over the past 20 years. The old treatments of urethral dilatation have largely been superseded by endoscopic incision (internal urethrotomy) or by formal reconstruction (urethroplasty). Urethral dilatation still has a place in elderly men with short strictures that recur infrequently and when the stricture is intimately related to the continence mechanism (such as the bladder neck stricture that follows radical prostatectomy). In these patients, occasional dilatation may be preferable to more complex procedures.

Internal urethrotomy cures around 50 per cent of short strictures. Success rates are highest when the stricture is short and when it is present within the bulbar urethra. In contrast, failure rates are highest in long strictures, strictures within the penile urethra and in recurrent strictures. In patients with recurrent strictures who are unable or unwilling to undergo urethroplasty, then intermittent self-dilatation with soft hydrophilic catheters on a regular (daily) basis can prevent stricture recurrence, although such self-dilatation is needed lifelong.

Short strictures with a clear traumatic history should be treated by urethroplasty since cure rates in excess of 90 per cent can be achieved by excision of the stricture with end to end anastomosis. Therefore, a conventional therapeutic algorithm is to offer an internal urethrotomy to all newly diagnosed strictures (excluding post-traumatic strictures), and to reserve the more major urethroplasty procedures for recurrent strictures.

Urethral dilatation
This is the old treatment for stricture. Under aseptic conditions, the urethra is stretched using graduated dilators. With care and gentleness, the procedure can be performed under local urethral anaesthesia with lignocaine gel. The drawback of dilatation is that it is performed 'blind', so there is always a danger of causing a false passage. This is most likely with an inexperienced operator unfamiliar with the complexities of an individual patient’s urethra.

Strictures have been treated by surgeons for centuries and there are many different dilating instruments. A simple stricture may be dilated using metal sounds (Figure 78.12), so called because they were originally used to ‘sound’ for stones in the bladder. These must be wielded with great care as it is easy to make a false passage.

Endoscopic (internal) urethrotomy
Internal urethrotomy is performed using the optical urethrotome. The stricture is cut under visual control using a knife passed through the sheath of a rigid ureteroscope. The stricture is usually cut at the 12 o’clock position, taking care not to cut too deeply into the vascular spaces of the corpus spongiosum that surrounds the urethra. Other cuts can be made
until there is a wide passage through the strictured segment of urethra. Many surgeons leave a catheter for 1–2 days afterwards. A single urethrotomy seems to give a permanent cure of an uncomplicated stricture in about 50 per cent of patients. The main complications are infection and bleeding. It is possible to get lost when trying to cut a way through a very tight stricture and this is especially true when there are false passages because of previous dilatation attempts. Accordingly, a guidewire should be passed through to the bladder prior to incision of the stricture in order to establish the true lumen of the urethra.

Urethroplasty
The simplest urethroplasty involves excision of the stenosed length of urethra and reanastomosis of the spatulated cut ends. This operation is possible only if the stricture is relatively short because there must be no tension at the suture line. If an end-to-end anastomosis is not feasible, a large number of different surgical procedures can be used to reconstruct the fibrosed urethra. The operations using myocutaneous flaps of penile and scrotal skin that dominated the field 20 years ago have largely been replaced by operations that utilise free grafts, usually of buccal mucosa, but also occasionally of penile skin, lingual mucosa and bladder mucosa. The advantage of buccal mucosa is that there is a plentiful supply (approximately 6–7 cm can be obtained from each cheek), it is tough with an excellent vascular plexus, it is used to being wet and the donor site cannot be seen. Indeed, the morbidity associated with the donor site is minimal.

Urethroplasty should be considered when the stricture has arisen following trauma, and when a stricture has recurred following endoscopic treatment. The actual technique used should depend upon the site of the stricture, the length of the stricture and the cause of the stricture. Careful preoperative assessment with ascending and descending urethrography is vital.

Anastomotic urethroplasty has a success rate of around 90 per cent while substitution urethroplasty has success rates at ten years of around 80 per cent (Summary box 78.6).

Summary box 78.6

**Treatment of urethral strictures**
- Newly diagnosed strictures are best treated initially by internal urethrotomy with a 50 per cent success rate
- Intermittent self-dilatation increases the success rate of internal urethrotomy alone
- Urethroplasty should be considered in traumatic strictures and in recurrent strictures
- Treatment by intermittent self-dilatation should be considered in strictures closely related to the external sphincter mechanism

OTHER CONDITIONS OF THE URETHRA

Urethral fistula
The most frequent cause of urethral fistula is bursting or incision of a periurethral abscess. If the fistula arises behind a tight stricture, there may be multiple openings (watering-can peri- neum). A fistula can also follow urethroplasty if there is necrosis of part of the graft or flap. The stricture should be treated, in which case some fistulae heal themselves. Occasionally, formal urethroplasty is indicated.

Urethral calculi
Urethral calculi can arise primarily behind a stricture or in an infected urethral diverticulum. More commonly, the stone is a renal calculus that has migrated to the urethra via the bladder.

Clinical features
Migratory calculi cause sudden pain in the urethra soon after an attack of ureteric colic. There is blockage to the flow of urine and, if the stone is small, the force of the jet will usually expel it from the urethral meatus. Larger stones get stuck and must be removed endoscopically. It is sometimes possible to feel the calculus as a hard lump in the urethra, but if there is doubt the diagnosis is confirmed by urethroscopy.

A stone formed within the urethra is less likely to cause recognisable symptoms and is usually detected during urethroscopy or bouginage.

Treatment
A stone lodged within the prostatic urethra should be displaced back into the bladder and treated by lithotripsy or suprapubic cystotomy as if it were a bladder stone. Calculi in more distal parts of the urethra are removed by baskets under vision or fragmented in situ using the electrohydraulic or ultrasonic lithotripter. It may be necessary to perform a meatotomy to deliver the stone. Open removal by external urethrotomy is rarely necessary.

Neoplasms
Polyps are a relatively common finding in the prostatic urethra, where they may result from chronic infection. Genital warts acquired by sexually transmitted infection are sometimes found in the anterior urethra as an extension of warts on the skin of the glans penis. Angioma of the urethra is a very rare cause of urethral bleeding.
Carcinoma of the urethra is relatively rare. Multifocal transitional cell cancers of the bladder are sometimes associated with tumours in the prostatic urethra and occasionally more distally. Though superficial and susceptible to local ablation by diathermy or laser, they are associated with a tendency to distant spread. Squamous carcinoma can develop in an area of squamous metaplasia sometimes seen with a urethral stricture. It carries a poor prognosis even if the patient is treated by radical surgery. Bloody urethral discharge without infection should raise the suspicion that the patient has a urethral tumour.

THE FEMALE URETHRA

Anatomy
The female urethra is around 2–3 cm long, extending from the bladder neck to the external urethral meatus. Continence is maintained by the external striated urethral sphincter, which in women extends for almost the whole length of the urethra. There is extra support from the surrounding pelvic floor musculature. In contrast to men, the female bladder neck has little role in the maintenance of continence.

Abnormalities of the female urethra include:
• prolapse
• stricture
• Fowler’s syndrome (dysfunction of the striated urethral sphincter)
• diverticulum
• caruncle
• papillomata acuminata
• carcinoma.

Prolapse (synonym: urethrocele)
Weakening of the tissues that hold the urethra in place can cause it to move and to put pressure on the vagina, leading to the prolapse of the anterior distal wall of the vagina. Urethroceles often occur with cystoceles. Prolapse occurs in later life and is usually, in part, due to the trauma of childbirth. Prolapse of the urethral lining also occurs as a congenital abnormality, when it causes discomfort proportional to the degree of prolapse.

Stricture
Urethral strictures are uncommon in women but may follow urethritis or more commonly the trauma of a difficult labour. Urinary retention is an occasional consequence and is usually chronic. True urethral strictures in women respond well to dilatation.

Fowler’s syndrome
This condition, which was described by Fowler and Kirby, is associated with an abnormal myotonic discharge in the striated urethral sphincter, which can be detected by electromyography. It causes urinary retention in women and should not be confused with a urethral stricture. Urethral dilatation is ineffective and the retention is best treated by intermittent self-catheterisation. There is some evidence that sacral neuromodulation can be effective.

Diverticulum
A urethral diverticulum is more commonly seen in women than in men. Some seem to be congenital while others are acquired by rupture of a distended urethral gland or injury of the urethra during childbirth. Urine within the diverticulum becomes infected, causing local pain and repeated bouts of cystitis. Purulent urine is discharged if the urethra is compressed with a finger placed in the vagina. Diagnosis is by magnetic resonance imaging (MRI) or by transvaginal ultrasound. Excision of the diverticulum through the anterior vaginal wall is effective, but care must be taken not to damage the urethral sphincter.

Caruncle
This is common in elderly women. It presents as a soft, raspberry-like, pedunculated granulomatous mass about the size of a pea, attached to the posterior urethral wall near the external meatus. It is composed of highly vascular connective tissue stroma infiltrated with pus cells. There may be frequency of micturition and urethral pain afterwards. Occasionally, there is bleeding. A urethral prolapse is less tender and is not pedunculated. Treatment is by excision and diathermy coagulation of the base of the stalk. The patient should be given antibiotics to treat the underlying chronic urethritis.

Papillomata acuminata
Papillomata acuminata are the same as the sexually transmitted warts that occur on the penis. They are treated in the same way. In African women, papillomata acuminata are common and may grow to such a large size during pregnancy that they obstruct labour and necessitate a caesarean section.

Carcinoma of the urethra
This occurs twice as often in women as in men. Whether a caruncle can become malignant is disputed, but caruncles and tumours often occur close together. Malignant swellings of the urethra feel harder than benign ones. Treatment by radiotherapy or radical surgery is often ineffective. The overall prognosis is poor.

THE PENIS

Anatomy
The penis is composed of three tubular structures. The upper two structures, which are apposed to each other, are called the corpora cavernosa and are anchored posteriorly onto the pubic rami. They provide the erectile function. The third tubular structure is the corpus spongiosum, which contains the urethra and it expands distally to form the glans penis. The corpora cavernosa have an outer covering of tunica albuginea which is relatively inelastic and which also forms the septum between them. The tunica albuginea encloses the erectile tissue itself which has

A caesarean section is the operation of delivering the fetus by an incision into the uterus, usually through the abdominal wall. More than one explanation has been given as the origin of the term. The word ‘caesarean’ could be a derivative of the Latin term ‘caedo’, which means to cut. The thought that it derives from the name of the Roman Emperor Julius Caesar is untrue as his mother Aurelia successfully gave birth to her son by natural means and later was an advisor to him. The most plausible explanation is that the Roman or Caesarean Law (law during Caesar’s time) demanded that when a pregnant woman died, her body could not be buried until the fetus had been removed."

a trabecular structure with a network of sinusoidal spaces lined by endothelium within which the blood pools during erection. The central arterial blood supply (the central penile artery) is a branch of the internal pudendal artery. Erection occurs when the parasympathetic nerves that innervate the penis cause smooth muscle relaxation with increased arterial inflow and dilatation of the sinusoids, such that blood accumulates within the trabecular spaces.

**DISEASES OF THE FORESKIN**

**Phimosis**

Phimosis is overdiagnosed in children (see also Chapter 8). At birth, the foreskin is normally adherent to the glans penis. These physiological adhesions between the foreskin and the glans penis may persist until six years of age or more, giving the false impression that the prepuce will not retract. This condition (sometimes known as physiological phimosis) should not be confused with true phimosis in boys, with scarring of the prepuce such that it will not retract without fissuring of the foreskin (Figure 78.13). In these cases, the aperture in the prepuce may be so tight as to cause urinary obstruction. Urinary difficulty with residual urine and back pressure effects on the ureters and kidney is far more commonly caused by meatal stenosis, which may be masked by the prepuce.

In adults, phimosis is due to scarring of the foreskin as a consequence of balanitis (inflammation of the glans penis), posthitis (inflammation of the foreskin), forcible retraction of the foreskin or lichen sclerosus et atrophicus (synonym: balanitis xerotica obliterans or BXO).

BXO is an uncommon condition in which the normally pliant foreskin becomes thickened. It typically becomes whitish in appearance and forms a constricting band (cicatrix) which prevents retraction (Figure 78.14a,b). BXO may also affect the glans penis (causing meatal stenosis) (Figure 78.15) and the penile urethra (causing urethral stricture). As a consequence it is difficult to keep the penis clean, there may be recurrent attacks of balanitis and there is both a problem with hygiene and, in later life, an increased susceptibility to carcinoma.

**Treatment.**

In a young child with a non-retractile foreskin, no treatment is necessary or appropriate. When the foreskin is mildly scarred, then preputioplasty is possible. For all other cases, circumcision is the appropriate treatment. In cases of BXO, circumcision is often curative, although when the condition affects the glans penis, topical steroid cream may be helpful. In resistant cases, formal meatotomy is necessary. In emergency situations, such as when catheterisation is required, but is impossible, then it is possible to divide the foreskin dorsally under local anaesthetic (a so-called dorsal slit).

**Preputioplasty**

This is an application of the Heineke Mikulicz principle whereby the tight ring of the foreskin is divided longitudinally and sewn transversely, thereby allowing retraction of the preserved foreskin. There is a recurrence rate and it is only indicated in mild cases with minimal scarring. If it fails, then circumcision is indicated.

**Circumcision**

Apparently, circumcision did not originate among the Jewish people: they took the practice either from the Babylonians or from African tribes, probably the latter. It had been practised in West Africa for over 5000 years.

**Indications**

In infants and young boys, circumcision is most usually performed at the request of the parents for social or religious reasons. Medical indications for circumcision in boys include true phimosis, BXO (rare under the age of five years), recurrent attacks of balanoposthitis and recurrent urinary tract infections with an abnormal upper urinary tract. Phimosis may result from misguided attempts by parents to expose the glans forcibly.

In adults, circumcision is indicated because of an inability to retract the foreskin for intercourse, for splitting of an abnormally tight frenulum or for recurrent balanitis.

Recently evidence has emerged that circumcision protects against the spread of human immunodeficiency virus (HIV), and a large scale programme of adult circumcision under the auspices of the World Health Organisation is planned for some African countries where HIV is a major health problem.

**Technique in an infant**

Applying a clamp or bone forceps across the prepuce distal to the glans with blind division of the foreskin is to be condemned. To see one boy with partial or total amputation of the glans is enough to realise the folly of this technique. It is far better to perform a proper circumcision under direct vision as in an adult.
The Plastibel device can be used in infants (Hollister) and its use is shown in Figure 78.16a–c: the ring separates between 5 and 8 days postoperatively.

**Technique in adolescents and adults**

In adolescents and adults, the following method is preferable. The prepuce is held in artery forceps and put on a gentle stretch. A circumferential incision in the penile skin is made at the level of the corona using a knife. Marking the skin with a pen is often helpful prior to the incision to ensure that excess skin is not removed. The prepuce is then slit dorsally in the midline to within 1 cm of the corona. This converts the foreskin into two flaps connected at the midline anteriorly. When the under-
surface of the prepuce has been separated from the glans, the inner layer of each flap is incised with a second circumferential incision, leaving about 0.5 cm of the inner layer of the prepu-
tial skin. Cutting the remaining connective tissue completes the excision (Figure 78.17a–e). Monopolar diathermy must be avoided in operations on the penis in small boys because there is a danger that the current path will cause coagulation at the base of the penis. Haemostasis is important in circumcision however, and vessels should be secured with bipolar diathermy or with absorbable ligatures. The cut edges of the skin are approximated using interrupted sutures being certain that the frenular vessels are ligated (Summary box 78.7).

**Summary box 78.7**

**Circumcision**

- Is most commonly performed for cultural reasons
- Is not indicated for failure of retraction caused by congenital adhesions between the glans penis and the prepuce
- Is indicated when there is true phimosis with balanoposthitis or obstruction to urinary flow
- Never use monopolar diathermy when performing circumcision

**Frenulum breve**

Phimosis should not be confused with this condition, where the frenulum is short, such that it causes pain when the foreskin is retracted. Another possible presentation is tearing of the frenulum during sexual activity. Treatment is by frenuloplasty, which utilises the Heineke Mikulicz principle to ‘lengthen’ the frenulum.

**Paraphimosis**

A tight foreskin once retracted may be difficult to return and a paraphimosis results. In this condition, the venous and lymphatic return from the glans and distal foreskin is obstructed and these structures swell, causing even more pressure within
the obstructing ring of prepuce. Icebags, gentle manual compression and injection of a solution of hyaluronidase in normal saline may help to reduce the swelling. Such patients can be treated by circumcision if careful manipulation fails. A dorsal slit of the prepuce under local anaesthetic may be enough in an emergency.

**Balanoposthitis**

Inflammation of the prepuce is known as posthitis; inflammation of the glans is balanitis. The opposing surfaces of the two structures are often involved, hence the term ‘balanoposthitis’. Skin conditions such as lichen planus and psoriasis affect the penis and, indeed, may be localised there. Drug hypersensitivity reactions can affect the skin of the penis. In mild cases, the only symptoms are itching and some discharge. In more severe inflammation, the glans and foreskin are red-raw and pus exudes. Balanoposthitis is associated with penile cancer, diabetes and phimosis. Monilial infections are quite common under the prepuce. Treatment is by broad-spectrum antibiotics and local hygiene measures. If there is associated phimosis, then a circumcision is required.

**Preputial calculi**

Later in life, chronic posthitis may lead to adhesions between the prepuce and the glans and closure of the orifice of the preputial sac. Preputial calculi result from the accumulation beneath a non-retractable foreskin of inspissated smegma, urinary salts or both.
INJURIES OF THE PENIS

Avulsion of the skin of the penis
Entanglement of clothing in rotating machinery is the usual cause. Repair is effected by burying the shaft of the penis in the scrotum with subsequent release at the time of a definitive plastic surgical repair.

Fracture of the penis
Fracture of the penis is an uncommon accident, usually occurring when the erect penis is bent violently downwards during intercourse. The forced deformity results in a rupture of the tunica albuginea with immediate extravasation of blood from within the penis. There is typically a loud cracking sound with immediate loss of the erection, and the rapid development of a large bruise around the penis and extending onto the scrotum (Figure 78.18). There may occasionally be an associated urethral injury. Optimal management involves early exploration of the penis with surgical repair of the ruptured tunica albuginea.

Strangulation of the penis
Strangulation of the penis by rings placed on the penis, usually for sexual reasons, can cause venous engorgement which prevents their removal. It may help to aspirate the corpora cavernosa but often the ring must be cut off with a ring cutter or hacksaw.

Other abnormalities of the penis

Erectile dysfunction
Failure to attain or maintain an erection is called erectile dysfunction (ED). It is a symptom, rather than a condition in itself. It can arise as a consequence of psychological issues, but the most common cause is vascular disease, and as such ED is associated with diabetes, hypertension, dyslipidaemia and smoking. Other rarer causes include endocrine disease (hypogonadism and prolactin secreting pituitary tumours), neurological disease (multiple sclerosis, spinal cord injury and prolapsed intervertebral disc), iatrogenic damage to the cavernosal nerves due to radical pelvic surgery (e.g. radical prostatectomy, abdomino-perineal excision of the rectum and radical cystectomy), neuropathy secondary to pelvic radiotherapy and drug-induced cases (including anti-hypertensive agents, antidepressants and antipsychotics).

Assessment involves confirmation of the diagnosis by taking a careful history, assessing the patient for underlying risk factors, and trying to identify the rare case that can be cured as opposed to being treated. Physical examination of the genitalia, the blood pressure and assessment of the secondary sexual characteristics is required and biochemical assessment of the blood sugar, the serum lipid profile and the serum testosterone is necessary in all cases.

Treatment for most patients involves the use of the phosphodiesterase type 5 inhibitors (such as sildenafil) with intracavernosal injection of prostaglandin, vacuum pumps and penile implants reserved for resistant cases (Summary box 78.8).

Peyronie’s disease
Peyronie’s disease is characterised by penile deformity (Figure 78.19), palpable penile plaques within the penis, erectile dys-

Summary box 78.8

Erectile dysfunction
- The most common cause of erectile dysfunction is atherosclerosis
- Appropriate investigation involves identification of vascular risk factors
- Phosphodiesterase inhibitors are the first line treatment for most men

function and pain on erection. The cause is unknown, but probably involves minor injury to the erect penis with secondary microhaemorrhage beneath the tunica albuginea and secondary fibrosis. The latter results in the palpable plaques that can be identified on examination. The plaques may rarely be calcified (Figure 78.20). The presence of these relatively inelastic plaques causes the erect penis to bend, often dramatically, towards the side of the plaque. The most common direction of deformity is dorsally (towards the abdomen) and the deformity may be so great as to prevent penetrative sexual intercourse.

While the aetiology is uncertain, there is an association with Dupuytren’s contracture. The natural history of the condition is that it typically progresses for 18–24 months before stabilising. During this active phase of the disease, surgery is not indicated, and a variety of medical treatments have been tried, although none with any good evidence of benefit.

When the disease has stabilised, the crucial issue is whether the patient is still able to have sexual intercourse. If he can then no treatment is indicated, while if the deformity prevents penetration, or makes it difficult, then corrective surgery is indicated. Using this criterion, only around a quarter of men come to surgery. The most common procedure is the Nesbitt procedure which corrects the deformity by plicating the convex side of the deformity, thereby straightening the penis, with some accompanying loss of length (Summary box 78.9).

Francois de la Peyronie, 1678–1747, surgeon to King Louis XIV of France, and founder of the Royal Academy of Surgery, Paris, France.
Reed Nesbitt, urological surgeon, Nashville, TN, USA.
Chordee

Chordee (French = corded) is a fixed bowing of the penis caused by hypospadias or, more rarely, chronic urethritis. Erection is deformed and sexual intercourse may be impossible. Treatment is usually surgical.

Priapism

Priapism means persistent erection lasting longer than 4 hours and it is a surgical emergency. There are two main types of priapism, ischaemic and non-ischaemic.

Ischaemic priapism

Ischaemic or venogenic priapism is the more common and is due to venous congestion, with consequent thrombosis and ischaemia. The penis remains erect and becomes painful. This is a pathological erection and the glans penis and corpus spongiosum are not involved. The condition is most commonly seen as a side effect of medication, most notably anti-psychotic medication and intracavernosal injections, but it can also arise as a complication of a hypercoagulable blood disorder such as sickle cell disease or leukaemia. A tiny proportion of cases are caused by malignant disease in the corpora cavernosa or the pelvis.

Non-ischaemic priapism

The rarer form of priapism arises as a consequence of traumatic damage to the central penile artery, usually as a consequence of blunt perineal trauma. A fistula develops between the artery and the sinusoidal space which results in a persistent erection, which in contrast to the ischaemic priapism is painless. Blood gas analysis shows arterial blood and Doppler scanning demonstrates the fistula (Figure 78.21a,b). Treatment is not an emergency, since there is no ischaemia, and is most appropriately achieved by selective arterial embolisation.

Carcinoma of the penis

Penile cancer is rare in the UK, with only around 600 cases being recorded annually. It is much more common in other parts of the world, most notably South America, where it is one of the most common cancers.
Aetiology

Circumcision soon after birth confers immunity against carcinoma of the penis. Later circumcision does not seem to have the same benefit, with the assumption that smegma is in some way carcinogenic. Human papillomavirus infection with penile warts is a risk factor, as is BXO and smoking. Phimosis and chronic balanoposthitis are known to be contributory factors, and there are definite precancerous states including leukoplakia of the glans, which is similar to the condition seen on the tongue, and carcinoma in situ of the penis.

Carcinoma in situ of the penis (synonym Bowen’s disease, erythroplasia of Queyrat)

Carcinoma in situ of the penis is typically seen as a red cutaneous patch on the penis. When it occurs on the glans penis, it is known as erythroplasia of Queyrat and when it occurs on the shaft of the penis it is called Bowen’s disease. There are several other benign causes of red patches on the penis, and when in doubt a biopsy is indicated. When the diagnosis of carcinoma in situ is confirmed, treatment is by means of topical 5-FU cream, CO₂ laser ablation or surgical excision.

Pathology

Carcinoma of the penis is most typically a squamous cell carcinoma arising in the skin of the glans or the prepuce. It may be flat and infiltrating or warty in appearance (Figure 78.22). The former often starts as leukoplakia and the latter results from an existing papilloma. Local growth continues for months or years. T1 tumours are confined to the skin, with T2 tumours invading the corpus spongiosum or the corpus cavernosum. T3 tumours invade the urethra and T4 tumours invade adjacent structures. The earliest lymphatic spread is to the inguinal (N1 and N2 disease) and then to the iliac nodes (N3 disease) (Figure 78.23). Distant metastatic deposits are infrequent.

Clinical features

Many patients present late (Figure 78.24), either because of embarrassment or because of misdiagnosis. About 10 per cent of patients are under 40 years of age. By the time the patient presents, the growth is often large and secondary infection causes a foul bloody discharge. There is typically little or no pain.

Around 50 per cent have inguinal lymph node enlargement at presentation, but the nodal enlargement often reflects infection. In many, the prepuce is non-retractile and must be split to view the lesion. A biopsy should be performed to make the diagnosis. Untreated, the whole glans may be replaced by a fungating offensive mass. Later, the inguinal nodes can erode the skin (Figure 78.23) of the groin and in rare cases death of the patient can result from erosion of the femoral or external iliac vessels.

Treatment

Management is divided into treatment of the primary tumour and treatment of the inguinal nodes. For the primary tumour surgical excision is the mainstay of treatment, with the tradi-
tional view that a 2 cm margin of normal tissue be removed being superceded by a more recent, more conservative view, such that penile preserving surgery with excision of much lower margins of normal tissue are now accepted. Tumours affecting the glans penis require glansectomy, with more advanced tumours requiring partial penectomy. In advanced cases, total penectomy is required with formation of a perineal urethrostomy. Such surgery is indicated even in advanced metastatic disease for reasons of local control.

Tumours affecting the glans penis require glansectomy, with more advanced tumours requiring partial penectomy. In advanced cases, total penectomy is required with formation of a perineal urethrostomy. Such surgery is indicated even in advanced metastatic disease for reasons of local control.

Treatment of any associated enlarged inguinal lymph nodes should be delayed until at least 3 weeks after local treatment of the primary lesion. Enlargement caused by infection will usually show signs of subsiding with antibiotic treatment. For palpable nodes, ultrasound-guided fine needle aspiration will confirm the diagnosis and a block dissection of both groins should be undertaken. The management of the nodes when there is no palpable disease is more controversial with most protocols dictating prophylactic lymph node dissection for tumours that are T2 or greater and for those that are poorly differentiated because of the risk of microscopic disease. A recent development is the use of sentinel node biopsy for palpable nodes in high risk cases.

Management of the pelvic nodes is even more controversial. When they are involved on computed tomography (CT) scanning, surgery probably has little role, but when the iliac nodes are not enlarged in the presence of N2 disease, the options are observation, pelvic lymphadenectomy or radiotherapy. The prognosis for tumours confined to the penis is good with five-year survival rates in excess of 80 per cent. With nodal involvement, the five-year survival rate falls to around 40 per cent (Summary box 78.11).

**Buschke–Löwenstein tumour**

Buschke–Löwenstein tumour is uncommon. It has the histological pattern of a verrucous carcinoma. It is locally destructive and invasive but appears not to spread to lymph nodes or to metastasise. Treatment is by surgical excision.

**Malignant melanoma of the penis**

This is an uncommon tumour, with the principles of management being the same as for squamous cell carcinoma. Blood-borne metastatic disease is, however, more common.

**SEXUALLY TRANSMITTED GENITAL INFECTIONS**

**Genital ulcers**

The most common cause of a genital ulcer is genital herpes. Other less common causes include syphilis and chancroid.

**Genital herpes**

Genital herpes is caused by sexual transmission of the herpes simplex virus (usually type 2, occasionally type 1). Recurrent attacks occur in 50 per cent or more of cases. Pain along the distribution of the sensory nerve, usually the genitofemoral nerve, precedes the eruption by 2 days and may be particularly severe around the anus. A group of tiny vesicles rapidly erodes to form shallow ulcers which are painful. The first attack is typically accompanied by fever and myalgia. In female patients, the ulcers often spread on to the thighs during the attack. Involvement of the urethra may cause retention of urine, which may persist for...
up to 14 days if there is radiculitis of the S2 and S3 nerve roots. The diagnosis is made clinically, or when there is doubt by either cell culture or by PCR-based techniques. Acyclovir and valacyclovir have been shown to be effective in treating genital herpes but they do not prevent recurrences.

A child born to a mother with active infection is susceptible to a fatal generalised herpes infection in the neonatal period. Caesarean section should be considered in these circumstances. There is an increased risk of carcinoma of the cervix and annual cytology for life is recommended.

**Syphilis**

Syphilitic ulcers are typically painless, rubbery and indurated. Due to the spirochaete *Treponema pallidum*, diagnosis was traditionally achieved by dark field microscopy, but modern serological techniques are nowadays more appropriate. The incidence of syphilis is increasing since the advent of the retrovirals used to treat HIV in mid-1990s. Treatment is by use of a long-acting penicillin.

**Lymphogranuloma venereum**

Lymphogranuloma venereum is a sexually transmitted disease caused by *Chlamydia trachomatis* (Chlamydia A) types L1–L3 and is primarily an infection of the lymphatics and lymph nodes. The primary lesion is a fleeting, painless, genital papule or ulcer which is often unnoticed by the patient. It can affect both sexes. While it was considered rare in developed countries, some recent outbreaks in Europe have occurred, usually in conjunction with HIV.

The inguinal glands become enlarged and painful between two and four months after infection. The masses of nodes mat together above and below the inguinal ligament to give the ‘sign of the groove’. The overlying skin reddens and there may be fluctuance. There may be a proctitis, which can go on to produce a rectal stricture if untreated. Lymphatic obstruction leads to lymphoedema in the perineum and occasionally the lower limbs. Urethritis and urethral stricture occur in men.

The diagnosis is confirmed clinically and by the detection of antibodies against the organism. Treatment is by a combination of antibiotics, which may include sulphonamides, oxytetracycline and erythromycin. The multilocular lymphatic masses should not be incised; aspiration is permissible to reduce discomfort.

**Granuloma inguinale**

This is a chronic and slowly progressive ulcerative tropical disease affecting the genitals and surrounding tissue but occasionally occurring elsewhere in the body. It is usually sexually transmitted and is caused by *Klebsiella granulomatis* and is most commonly seen among socially deprived people. The incubation period varies greatly but is typically between 7 and 30 days.

A painless vesicle or indurated papule, usually on the external genitals but occasionally elsewhere on the skin, gradually erodes into a slowly extending ulcer with a beefy-red, granulomatous base. More chronic lesions may become greyish, especially at the edges, where, after months or years, malignant change may develop. The ulcerated area may bleed if touched but is usually surprisingly painless. Without treatment, healing is only partial and keloid is common.

Diagnosis is by microscopy of material from the edges of the ulcer, which shows the presence of short Gram-negative rods within the cytoplasm of the large mononuclear cells. Treatment is by erythromycin, oxytetracycline or streptomycin.

**Condylomata acuminata (synonym: genital warts)**

Genital warts are caused by infection with human papillomavirus (HPV) and are sexually transmitted. Infection is very common with only a small proportion of infected patients actually having visible warts. Most commonly due to HPV types 6 and 11, these viruses do not cause cervical cancer. Ordinary skin warts can occur on the genitals by direct contact with a finger lesion, but they are less moist and soft and less often pedunculated than the genital variety. The lesions most commonly occur under the prepuce in the coronal sulcus but may be found elsewhere, including inside the urinary meatus (Figure 78.25). In women, genital warts are most commonly found on the vulva but they may line the vagina and occur on the cervix. Perianal warts are common.

Other associated sexually transmitted diseases should be excluded: in women mainly candidiasis and Trichomonas infection and in men syphilis or gonorrhoea. Genital warts may complicate HIV infection.

Treatment is by chemical or physical means. Podophyllin is often effective as a topical application. It is applied to the wart, taking great care to avoid the surrounding skin, and washed off after 6 hours or so. An alternative agent is Imidaquod. If chemical methods fail, the warts can be excised or they can be ablated with cryosurgery, electrosurgery or laser. Circumcision is sometimes advised if there are florid lesions under the foreskin.

**Figure 78.25** Penile warts.

Testis and scrotum

LEARNING OBJECTIVES

To recognise and understand:
- Testicular maldescent and to appreciate the reasons for intervention
- Testicular torsion as a urological emergency
- The management of the common scrotal swellings (varicocele, hydrocele and epididymal cysts)
- The management of testicular tumours
- The treatment options for infertile men

EMBRYOLOGY AND ANATOMY OF THE TESTIS

The testes develop in the retroperitoneum below the kidneys at around the 10th thoracic level. During the 7th week of fetal development, the gubernaculum forms within the folds of the peritoneum. The upper end is attached to the developing testis and the lower end is attached to the fascia between the developing abdominal wall muscles. At the same time an evagination of the peritoneum itself, the processus vaginalis, develops adjacent to the gubernaculum and over the subsequent weeks evaginates through the abdominal wall to create the inguinal canal. The processus vaginalis initially picks up fibres of the internal oblique (which become the cremasteric muscle) and then fibres of the external oblique (which become the external spermatic fascia). As it elongates, the processus carries with it the gubernaculum, which contains muscle fibres, although it is not fully clear what part it plays in testicular descent. What is clear is that the testes lie at the internal inguinal ring at three months’ gestation and descend to the scrotum between seven and nine months. This latter descent into the scrotum is accompanied by shortening of the gubernaculum. Final descent from the external ring to the base of the scrotum takes 4–6 weeks and is usually complete by birth.

The mechanisms that result in testicular descent are poorly understood but probably involve Müllerian inhibiting substance. Maternal chorionic gonadotrophin stimulates growth of the testis and may stimulate its migration. Imperfectly developed testes tend to descend incompletely.

The anatomy of the adult testis reflects its embryonic development. The testicular arteries originate high up in the retroperitoneum from the abdominal aorta, just below the renal arteries. The testicular veins drain into the renal vein on the left and the inferior vena cava on the right. For much of their course, the testicular artery and vein run parallel to the ipsilateral ureter, for which they may be mistaken during retroperitoneal surgery.

The epididymis lies on the posterior aspect of the testis and is palpable as a separate structure, with a head, a body and a tail. The seminiferous tubules enter the epididymis at the upper end of the epididymis (the head). From the head, sperm travel through the body and tail of the epididymis to enter the vas deferens at the lower pole of the testis. The vas curves up behind the testis and can be felt above the testis as a firm tubular structure entering the external inguinal ring. In the inguinal canal, the vas deferens is invested by the cremasteric muscle along with the other components of the spermatic cord.

INCOMPLETELY DESCENDED TESTIS

Definitions

Incomplete descent of the testis occurs when the testis is arrested in some part of its normal path to the scrotum. An ectopic testis is a testis that is abnormally placed outside this path (see also Chapter 8).

Incidence

About 4 per cent of boys are born with one or both testes incompletely descended. About two thirds of these reach the scrotum during the first three months of life, but full descent after that is uncommon. The incidence of testicular maldescent at the age of one year is around 1 per cent. The condition is sometimes missed in the neonatal period and only discovered later in life. In a few cases, the presence of a hernia, testicular pain or acute torsion directs attention to the abnormality. In 10 per cent of unilateral cases, there is a family history.

True testicular pain can be situated in the lower abdomen at the level of the internal inguinal ring in accordance with Brown’s Law. Francis Robert Brown, former Reader in Surgery, St Andrews’s University, UK. Brown’s Law: Pain, produced in an organ which has migrated from its primary position, and which has not acquired an additional nerve supply in its secondary or permanent position, is invariably localised in the primary relative of that organ.

Sir Astley Cooper, 1768–1841, surgeon, Guy’s Hospital, London and First President of the Royal College of Surgeons of England, taught that patients with bilateral retained testes were usually sterile, whereupon one of his pupils, a cryptorchid, left the room and committed suicide. At the post-mortem mottled spermatozoa were demonstrated.
**Pathology**

The condition is more common on the right and is bilateral in 20 per cent of cases. In adults, secondary sexual characteristics are typically normal.

The testis may be:

- intra-abdominal; usually lying extraperitoneally just inside the internal inguinal ring;
- intra-canalicular; it may or may not be palpable (Figure 79.1);
- extra-canalicular; usually at the scrotal neck;
- ectopic; the most common site is within the superficial inguinal pouch which lies just inferior and medial to the superficial inguinal ring. Other rarer ectopic sites include the femoral triangle, the root of the penis and perineum.

Incompletely descended testes are often macroscopically normal in early childhood, but by puberty the testis is typically smaller compared with its intrascrotal counterpart. Microscopic changes are apparent from 1–2 years, including loss of Leydig cells, degeneration of Sertoli cells and decreased spermatogenesis. The higher the testis, the greater the degree of histological change.

**Consequences**

**Infertility**

Impaired fertility is a well-recognised consequence of testicular maldescent with paternity rates around two-thirds of normal for unilateral undescended testes and one-third of normal for bilateral undescended testes. Although there has been a recent tendency to undertake surgical orchidopexy earlier in life, evidence to show that this might benefit fertility is currently lacking.

**Malignancy**

The cancer risk for adults after cryptorchidism in childhood is 5–10 times greater than normal. The most common cancer is a seminoma and, as with fertility, it is unclear whether early orchidopexy reduces the risk of malignancy. However, if a testicular tumour does develop, it is undoubtedly easier to identify in a testis that is within the scrotum.

**Hernia**

Around 90 per cent of boys with an undescended testis have a patent processus vaginalis, although the incidence of a clinically apparent hernia is much lower.

**Testicular torsion**

The undescended testis is more prone to testicular torsion, largely as a consequence of a developmental abnormality between the testis and its mesentery (Summary box 79.1).

**Summary box 79.1**

- Testes that are absent from the scrotum after three months of age are unlikely to descend
- Histological changes in the testis can be seen from one year of age
- An incompletely descended testis tends to atrophy as puberty approaches
- Boys with undescended testes are at greater risk of infertility, testicular malignancy, hernia and testicular torsion

**Clinical features**

During childhood, the testes are mobile and the cremasteric reflex is active. In some boys, any stimulation of the skin of the scrotum or thigh causes the testis to ascend and to temporarily disappear into the inguinal canal. This is called a retractile testis. In comparison to a true undescended testis, the scrotum of a boy with a retractile testis is normal as opposed to underdeveloped. When the cremaster relaxes, the testis reappears only to vanish when the scrotal skin is touched again. A retractile testis can be gently milked from its position in the inguinal region to the bottom of the scrotum. A diagnosis of true incomplete descent should be made only if this is not possible. It is helpful to have the boy as relaxed as possible and for him to be examined in a warm room, usually in a supine position.

When the testis is impalpable, ultrasound may be helpful in identifying the intracanalicular testis, while laparoscopy may be needed to differentiate between the abdominal testis and a truly absent testis (Summary box 79.2).

**Summary box 79.2**

- Retractile testes should be differentiated from true undescended testes
- This is most easily done with the child relaxed in a warm room
- Retractile testes are more common than true undescended testes
- Retractile testes require no treatment

**Surgical treatment**

**Orchidopexy**

Orchidopexy is usually performed before the boy reaches 12 months of age in an attempt to prevent the consequences described earlier. The testis and spermatic cord are mobilised...
and the testis is repositioned in the scrotum. The operation is performed through a short incision over the deep inguinal ring. The inguinal canal is exposed by division of the external oblique aponeurosis in the direction of its fibres.

Three manoeuvres help to gain the length required to bring the testis down into the bottom of the scrotum. First the patent processus vaginalis should be identified, separated and ligated. Second the coverings of the spermatic cord (including the cremasteric muscle) should be divided and third, lateral fibrous bands just inside the internal inguinal ring should be divided. Although these techniques are usually effective, the tiny vas and testicular vessels are vulnerable to injury. The empty hemiscrotum is stretched with a finger passed into it through the inguinal incision to give enough room for the testis which is placed in a pouch constructed between the dartos muscle and the skin (Figure 79.2).

**Failure to bring the testis down**

Sometimes for a high undescended testis a two-stage surgical procedure is necessary. The testis is mobilised as far as possible and anchored with a suture and the mobilisation is completed six months later. An alternative approach involves initial division of the gonadal artery (which is usually ‘tighter’ than the vas deferens), such that the testis becomes dependent for its blood supply upon the vasal artery. The second stage procedure involves conventional orchidopexy. Orchidectomy should be considered if the incompletely descended testis is atrophic, particularly in the post-pubertal boy if the other testis is normal.

**INJURIES TO THE TESTIS**

The testis can be damaged either by blunt or by penetrating trauma. Injuries can range from simple bruising, through significant intra-testicular haematoma to rupture of the tunica albuginea with very significant collections of blood within the tunica vaginalis (haematocoele) (Figure 79.3). If the tunica ruptures, the blood can track into the groin and perineum. Ultrasound examination is a useful adjunct to clinical examination and surgical exploration is indicated for significant injuries including testicular rupture. The objective is to repair the tunica albuginea and preserve the testis, but on occasions orchidectomy is necessary (Summary box 79.3).

**Summary box 79.3**

**Scrotal trauma**

- Scrotal exploration should be considered when there is massive swelling and pain after scrotal trauma
- Ultrasound is valuable in the assessment of the injury

**ABSENT TESTIS**

‘Vanishing’ testis describes a condition in which a testis develops but disappears before birth. The most likely cause for this is prenatal torsion. True agenesis of the testis is rarer. Laparoscopy is useful in distinguishing these causes of clinically absent testis from intra-abdominal maldescent.

**TORSION OF THE TESTIS**

**Pathophysiology**

Testicular torsion is a condition whereby the testicle twists in such a way that its blood supply becomes compromised. If left untreated, the blood flow to the testicle ceases and the testicle dies. The earlier the surgery to untwist the testis can be undertaken the better the results, with a testicular salvage rate of 100 per cent if the testicle can be untwisted within 6 hours of the torsion taking place compared with an approximate 20 per cent salvage rate if the surgery is delayed for 24 hours.

Torsion of the testis is uncommon because the normal testis is anchored and cannot rotate. For torsion to occur, one of several abnormalities must be present:

- Inversion of the testis is the most common predisposing cause. The testis is rotated so that it lies transversely or upside down.
- High investment of the tunica vaginalis causes the testis to hang within the tunica like a clapper in a bell (Figure 79.4).
- Separation of the epididymis from the body of the testis permits torsion of the testis on the pedicle that connects the testis with the epididymis (Figure 79.5).

Normally, when there is a contraction of the abdominal muscles, the cremaster contracts as well. In the presence of one of the abnormalities described above, the spiral attachment of...
the cremaster favours rotation of the testis around the vertical axis. Straining on stool, lifting of a heavy weight and coitus are all possible precipitating factors. Alternatively, torsion may develop spontaneously during sleep.

**Clinical features**

Testicular torsion is most common between 10 and 25 years of age, although a few cases occur in infancy. Typically, there is sudden agonising pain in the groin and the lower abdomen. The patient feels nauseated and may vomit. Torsion of a fully descended testis is usually easily recognised. The testis seems high and the tender twisted cord can be palpated above it. The cremasteric reflex is lost.

**Differential diagnosis**

Redness of the skin and a mild pyrexia may result in the condition being confused with epididymo-orchitis in the older patient; however, in epididymo-orchitis there will usually be dysuria associated with the accompanying urinary infection. Elevation of the testis reduces the pain in epididymo-orchitis and makes it worse in torsion.

Torsion of a testicular appendage cannot always be distinguished with certainty from testicular torsion. The most common structure to twist is the appendix of the testis (the pedunculated hydatid of Morgagni). The twisted testicular appendages can sometimes be visible through the scrotal wall. If the diagnosis is made clinically, then conservative management is possible, but if in doubt then surgical exploration should be undertaken with ligation and amputation of the twisted appendage.

**Management**

The management of the case should be determined primarily on clinical grounds. If there is any doubt as to the diagnosis, then urgent scrotal exploration is indicated. While Doppler ultrasound scanning can confirm the absence of the blood supply to the affected testis, false positive results can be seen, so it is not routinely recommended.

Exploration for torsion should be performed through a scrotal incision. If the testis is viable when the cord is untwisted it should be prevented from twisting again by fixation with non-absorbable sutures between the tunica vaginalis and the tunica albuginea. The other testis should also be fixed because the anatomical predisposition is likely to be bilateral. An infarcted testis should be removed – the patient can be counselled later about a prosthetic replacement.

In cases where there is a history of pain for several days, the affected testis will be dead. It is not possible to recover such a testis and although little is gained (other than pain relief) by immediate exploration it is necessary to fix the contralateral testis (Summary box 79.4).

**VARICOCELE**

A varicocele is a varicose dilatation of the veins draining the testis.

**Surgical anatomy**

The veins draining the testis and the epididymis form the pampiniform plexus. The veins gradually join each other as they traverse the inguinal canal and, at or near the inguinal ring, there are only one or two testicular veins, which pass upwards...
within the retroperitoneum. The left testicular vein empties into the left renal vein, the right into the inferior vena cava below the right renal vein. The testicular veins usually have valves near their terminations, but these are sometimes absent. There is an alternative (collateral) venous return from the testes through the cremasteric veins, which drain mainly into the inferior epigastrics.

**Aetiology**

Varicoceles are common, affecting perhaps 15–20 per cent of males. Ninety per cent are left-sided, reflecting the proximal venous anatomy. In some cases, the dilated vessels are cremasteric veins and not part of the pampiniform plexus. The usual cause is absence or incompetence of valves in the proximal testicular vein. While most varicoceles are idiopathic, obstruction of the left testicular vein by a renal tumour or nephrectomy is a cause of varicocele in later life; characteristically, in such cases the varicocele does not decompress in the supine position.

**Clinical features**

While most varicoceles are asymptomatic, those that are symptomatic tend to present in adolescence or early adulthood when there may be an annoying dragging discomfort that is worse on standing at the end of the day. This presumably reflects distension of the testicular veins. When examined in the erect position, the scrotum on the affected side hangs lower than normal (Figure 79.7), and on palpation, with the patient standing, the varicose plexus feels like a bag of worms. There may be a cough impulse. If the patient lies down the veins empty by gravity and this provides an opportunity to ensure that the underlying testis is normal to palpation. In longstanding cases, the affected testis is smaller and softer than its fellow owing to a minor degree of atrophy.

Ultrasonography can be helpful in the diagnosis of small varicoceles (Figure 79.8) and in older men with an apparently recent onset of varicocele, ultrasonography of the kidneys is important in excluding a left renal tumour.

**Varicocele and spermatogenesis**

Of all the possible causes of primary infertility, oligozoospermia (reduced numbers of sperm in the ejaculate) is one of the most difficult to treat. Because varicoceles are relatively common, some men with oligozoospermia will have a varicocele, and it is tempting to blame this for the infertility. Certainly the varicocele will tend to ‘warm’ the testis, which is usually around 2.5ºC below rectal temperature, and there is conflicting evidence regarding the effect of this temperature difference upon spermatogenesis. Unfortunately, there is little evidence that varicocelectomy improves semen quality or the rate of conception.

**Treatment**

Operation is not indicated for an asymptomatic varicocele. When the discomfort is significant, then embolisation of the gonadal veins is the usual first line intervention. If this is not possible, or if the varicocele recurs (as it does in around 20 per cent after embolisation), then surgical ligation of the testicular veins is the appropriate treatment, although recurrence can occur even after such surgery (Summary box 79.5).

---

**Summary box 79.4**

**Testicular torsion**
- If the diagnosis of testicular torsion is possible, then surgical exploration is indicated
- Prompt exploration, untwisting and fixation is the only way to save the torted testis
- The patient should be counselled and consented for orchidectomy before exploration
- The anatomical abnormality is bilateral and the contralateral testis should also be fixed

---

**Summary box 79.5**

**Varicocele**
- Varicocele is a common condition and 90% are left sided
- Development of a left-sided varicocele in later life may indicate the presence of a renal tumour
- They are usually asymptomatic and as such rarely need treatment
- First-line treatment is embolisation in symptomatic cases
- Varicoceles often recur, even after surgical treatment
- The association of varicoceles with subfertility is controversial
HYDROCELE

A hydrocele is an abnormal collection of serous fluid in a part of the processus vaginalis, usually the tunica vaginalis. Acquired hydroceles are primary or idiopathic, or secondary to epididymal or testicular disease.

**Aetiology**

A hydrocele can be produced in four different ways (Figure 79.9):

1. By excessive production of fluid within the sac, e.g. a secondary hydrocele
2. By defective absorption of fluid; this appears to be the explanation for most primary hydroceles, although the reason why the fluid is not absorbed is obscure
3. By interference with lymphatic drainage of scrotal structures
4. By connection with the peritoneal cavity via a patent processus vaginalis (congenital).

Hydrocele fluid contains albumin and fibrinogen. If the contents of a hydrocele are allowed to drain into a collecting vessel, the liquid does not clot; however, the fluid coagulates if mixed with even a trace of blood that has been in contact with damaged tissue.

A secondary hydrocele is most frequently associated with acute or chronic epididymo-orchitis. It is also seen with torsion of the testis and with some testicular tumours. A secondary hydrocele is usually lax and of moderate size: the underlying testis is palpable. If a tumour is suspected, the hydrocele should not be punctured for fear of needle-track implantation of malignant cells. A secondary hydrocele subsides when the primary lesion resolves.

**Clinical features**

Hydroceles are typically translucent and it is possible to ‘get above the swelling’ on examination of the scrotum. The swelling usually surrounds the testis and epididymis such that they may become impossible to palpate separately.

A primary vaginal hydrocele is seen most commonly in middle and later life but can also occur in older children. The condition is particularly common in hot countries. Because the swelling is usually painless it may reach a prodigious size before the patient presents for treatment. The testis may be palpable within a lax hydrocele, but an ultrasound scan is necessary to visualise the testis if the hydrocele sac is tense. Be wary of an acute hydrocele in a young man since there may be a testicular tumour.

In congenital hydrocele, the processus vaginalis is patent and connects with the peritoneal cavity. The communication is usually too small to allow herniation of intra-abdominal contents. Pressure on the hydrocele does not always empty it but the hydrocele fluid may drain into the peritoneal cavity when the child is lying down; thus, the hydrocele may be intermittent. Ascites should be considered if the swellings are bilateral.

Encysted hydrocele of the cord is a smooth oval swelling near the spermatic cord, which is liable to be mistaken for an inguinal hernia. The swelling moves downwards and becomes less mobile if the testis is pulled gently downwards.

Hydrocele of the canal of Nuck is a similar condition in females. The cyst lies in relation to the round ligament and is always at least partially within the inguinal canal.

**Treatment**

Congenital hydroceles are treated by herniotomy if they do not resolve spontaneously (see Chapter 8).

Small acquired hydroceles do not need treatment. If they are sizeable and bothersome for the patient, then surgical treatment is indicated. Established acquired hydroceles often have thick walls. Unless great care is taken to stop bleeding after excision of the wall, haemorrhage from the cut edge is liable to cause a large scrotal haematoma. Lord’s operation is suitable when the sac is reasonably thin-walled (Figure 79.10). There is minimal dissection and the risk of haematoma is reduced. Eversion of the sac with placement of the testis in a pouch prepared by dissection in the fascial planes of the scrotum is an alternative (Jaboulay’s procedure) (Figure 79.11).

Aspiration of the hydrocele fluid is simple, but the fluid always reaccumulates within a week or so. It may be suitable for men who are unfit for scrotal surgery, although hydrocele surgery can be undertaken under local anaesthetic. Aspiration can result in bleeding into the hydrocele sac and haematoma formation. Injection of sclerosants such as tetracycline is effective but painful (Summary box 79.6).

**Filarial hydroceles and chyloceles**

Filarial hydroceles and chyloceles account for up to 80 per cent of hydroceles in tropical countries where the parasite *Wuchereria bancrofti* is endemic. Filarial hydroceles follow repeated attacks...
Cysts associated with the epididymis

1383

of filarial epididymo-orchitis. They vary in size and may develop slowly or very rapidly. Occasionally, the fluid contains liquid fat, which is rich in cholesterol. This is caused by rupture of a lymphatic varix with discharge of chyle into the hydrocele. In longstanding chyloceles, there are dense adhesions between the scrotum and its contents. Filarial elephantiasis supervenes in a small number of cases. Treatment is by rest and aspiration. The more usual chronic cases are treated by excision of the sac.

Haematocele
The most common cause of a haematocele is vessel damage during needle drainage of a hydrocele. Prompt refilling of the sac associated with pain, tenderness and reduced transillumination will confirm the diagnosis. Acute haemorrhage into the tunica vaginalis sometimes results from testicular trauma with or without testicular rupture. If the haematocele is not drained, the blood within it clots (Figure 79.12). It becomes painless and may be mistaken for a testicular tumour. Indeed, a tumour may present as a haematocele. Ultrasound scanning usually helps with the differential diagnosis.

Cysts of a testicular appendage
Cysts of a testicular appendage are usually unilateral and are felt as small globular upper pole swellings. Such cysts are liable to torsion and should be removed if they cause symptoms. They are usually very small.

Spermatocele
This is a unilocal retention cyst derived from some portion of the sperm-conducting mechanism of the epididymis. A spermatocele typically lies in the epididymal head above and behind the upper pole of the testis. It is usually softer and laxer than other cystic lesions in the scrotum but, like them, it transilluminates. The fluid contains spermatozoa and resembles barley water in appearance. Spermatoceles are usually small and unobtrusive. Small spermatoceles can be ignored. Larger ones should be aspirated or excised through a scrotal incision (Summary box 79.7).

Summary box 79.6

Hydrocele
- A hydrocele is a collection of fluid within the tunica vaginalis
- Primary hydroceles surround the testis and transilluminate brightly
- Ultrasound examination is valuable when the testis and epididymis are impalpable
- Hydroceles can be treated conservatively unless they are large and symptomatic
- Surgery is the mainstay of treatment
- Testicular malignancy is an uncommon cause of hydrocele that can be excluded by ultrasound examination

Epididymal cysts
These are filled with a crystal-clear fluid. They are very common, usually multiple and vary in size at presentation. They represent cystic degeneration of the epididymis. Cysts of the epididymis are usually found in middle age and are often bilateral. The clusters of tense cysts feel like tiny bunches of grapes that lie posterior to and quite separate from the testis. They should transilluminate brilliantly. The diagnosis can be confirmed by ultrasound (Figure 79.13).

Aspiration is useless because the cysts are usually multilocular. If they are causing discomfort, they should be excised. While single large cysts can be excised separately, recurrent or multilocular cysts usually require partial or total epididymectomy. Excision should be expected to interfere with the transportation of sperm from the testis on that side and young men should be counselled regarding this.

Cysts of the testicular appendage
Cysts of the testicular appendage are usually unilateral and are felt as small globular upper pole swellings. Such cysts are liable to torsion and should be removed if they cause symptoms. They are usually very small.

Spermatocele
This is a unilocal retention cyst derived from some portion of the sperm-conducting mechanism of the epididymis. A spermatocele typically lies in the epididymal head above and behind the upper pole of the testis. It is usually softer and laxer than other cystic lesions in the scrotum but, like them, it transilluminates. The fluid contains spermatozoa and resembles barley water in appearance. Spermatoceles are usually small and unobtrusive. Small spermatoceles can be ignored. Larger ones should be aspirated or excised through a scrotal incision (Summary box 79.7).

Mathieu Jaboulay, 1860–1913, Professor of Surgery, Lyons, France.

A patient with a spermatocele often complains that he has a ‘third testicle’. He feels lucky that he is unduly provided! The story goes that, in the 14th century, on petition from a patient with a spermatocele, the Pope granted a gentleman to marry two wives because he had ‘three testicles’.

Figure 79.11 Jaboulay’s procedure. The hydrocele sac is everted and anchored with sutures.

Figure 79.12 A longstanding haematocele. The testis has been flattened by prolonged pressure.
EPIDIDYMO-ORCHITIS

Inflammation confined to the epididymis is epididymitis; infection spreading to the testis is epididymo-orchitis.

Pathophysiology

Infection reaches the epididymis via the vas from a primary infection of the urethra, prostate or seminal vesicles. A general rule is that epididymitis arises in sexually active young men from a genital infection, while in older men it more usually arises from a urinary infection or may be secondary to an indwelling urethral catheter.

In young sexually active men, the most common cause of epididymitis is now *Chlamydia trachomatis*, but gonococcal epididymitis is still occasionally seen. In older men with bladder outflow obstruction, epididymitis may result from a urinary infection – it is proposed that a high pressure in the prostatic urethra might cause reflux of infected urine up the vasa. Blood-borne infections of the epididymis are less common but may be suspected when there is *Escherichia coli*, streptococcal, staphylococcal or *Proteus* infection without evidence of urinary infection and are presumably the only possible mechanism in men who have previously undergone a vasectomy. Acute epididymo-orchitis can follow any form of urethral instrumentation. It is particularly common when an indwelling catheter is associated with infection of the prostate.

Clinical features

While there may be initial symptoms of a urinary or a genital infection, such symptoms are not always seen. The development of an ache in the groin and a fever can herald the onset of epididymitis. The epididymis and testis swell and become painful. The scrotal wall, at first red, oedematous and shiny, may become adherent to the epididymis. Urinalysis will usually show leukocytes and may show a formal urinary tract infection. Ultrasound is useful in the initial assessment of epididymitis and will identify abscess formation. In young men, urethral swabs should be taken for chlamydial testing.

In adolescents the differential diagnosis is testicular torsion and if there is any clinical doubt as to the diagnosis then testicular exploration should be performed.

Resolution may take 6–8 weeks to complete. Occasionally, an abscess can form that needs surgical drainage. Other complications include testicular atrophy, development of a chronic epididymitis and infertility.

Treatment

Either doxycycline (100–200 mg daily) or a quinolone should be the initial treatment in young men. There should be contact tracing of the partner and treatment if necessary.

In older men, quinolones are the usual initial treatment but if there is evidence of systemic sepsis, then intravenous antibiotics directed at urinary pathogens may be valuable. If an organism is isolated from the urine, this simplifies the choice of antibiotic.

All patients should drink plenty of fluid. Local measures including scrotal support and analgesia are helpful. Antibiotic treatment should continue for at least 2 weeks or until the inflammation has subsided. If suppuration occurs, drainage is necessary.

Chronic disease

Chronic non-tuberculous epididymitis usually follows the failure of resolution of an acute episode of epididymitis. Patients typically complain of intermittent episodes of discomfort and the epididymis feels thickened and tender. Treatment involves use of antibiotics (usually quinolones or doxycycline) and anti-inflammatory agents for 4–6 weeks. Epididymectomy or orchidectomy can be considered if there is no resolution although some patients continue to suffer from pain despite such surgery (Summary box 79.8).

Summary box 79.8

**Acute epididymo-orchitis**

- In young men usually arises secondary to a sexually transmitted genital infection
- In older men usually arises secondary to urinary infection
- May be a complication of catheterisation or instrumentation of the urinary tract
- May need aggressive treatment with parenteral antibiotics

**TUBERCULOUS EPIDIDYMO-ORCHITIS**

Chronic tuberculous epididymo-orchitis usually begins insidiously. The frequency with which the lower pole of the epididymis is involved first indicates that the infection is retrograde from a tuberculous focus in the seminal vesicles.

Clinical features

Typically, there is a firm, uncomfortable discrete swelling of the lower pole of the epididymis. The disease progresses until the...
whole epididymis is firm and craggy behind a normal-feeling testis. There is a lax secondary hydrocele in 30 per cent of cases, and a characteristic beading of the vas may be apparent as a result of subepithelial tubercles. The seminal vesicles feel indurated and swollen. In neglected cases, a tuberculous ‘cold’ abscess forms, which may discharge. The body of the testis may be uninvolved for years, but the contralateral epididymis often becomes diseased. In two-thirds of cases, there is evidence of renal tuberculosis or previous disease. Otherwise, patients typically appear healthy.

The urine and semen should be examined repeatedly for tubercle bacilli in all patients with chronic epididymo-orchitis. A chest x-ray should be performed as should imaging of the upper urinary tract. Ultrasound will demonstrate a thickened epididymis.

**Treatment**

Secondary tuberculous epididymitis may resolve when the primary focus is treated.

Treatment with anti-tuberculous drugs is less effective in genitai tuberculosis than in urinary tuberculosis. If resolution does not occur within two months, epididymectomy or orchidectomy is advisable. A course of anti-tuberculous chemotherapy should be completed even if there is no evidence of disease elsewhere.

**ORCHITIS**

Mumps orchitis, which is the most common form of orchitis, develops in 20–30 per cent of post-pubertal patients with a mumps virus infection and it usually develops as the parotid swelling is waning. Evidence of IgM antibodies in the serum supports the diagnosis. The main complication is testicular atrophy, which may cause infertility if the condition is bilateral. Partial testicular atrophy is associated with persistent testicular pain.

Syphilitic orchitis is now uncommon. It can cause bilateral orchitis (which is a feature of congenital syphilis), interstitial fibrosis, which causes painless destruction of the testis or rarely it may lead to a gumma of the testis, which presents as an unilateral slowly growing painless swelling. The latter presentation may be difficult to distinguish from a neoplasm without surgical exploration. Diagnosis is confirmed by serology.

**TUMOURS OF THE TESTES**

Testicular cancer represents around 1–1.5 per cent of male neoplasms and there is clear evidence of an increased incidence of these tumours in the past 30 years. The vast majority are germ cell tumours and the peak incidence of seminomas is in the fourth decade of life with the non-seminomatous germ cell tumours being more common in the third decade of life. They are the most common form of tumour in young men. Risk factors include a history of testicular maldescent, a history of a contralateral testicular tumour and Klinefelter’s syndrome.

**Classification and pathology**

Tumours of the testis are classified according to their predominant cellular type:

- germ cell tumours (90–95% per cent) (these include seminoma, embryonal cell carcinoma, yolk sac tumor, teratoma, and choriocarcinoma);
- interstitial tumours (1–2 per cent) (these include Leydig cell tumours);
- lymphoma (3–7 per cent);
- other tumours (1–2 per cent).

**Seminoma**

A seminoma typically has a cut surface which is homogeneous and pinkish cream in colour. It appears to compress neighbouring testicular tissue (Figure 79.14). It consists of oval cells with clear cytoplasm and large, rounded nuclei with prominent acidophilic nucleoli. Sheets of cells resembling spermatocytes are separated by a fine fibrous stroma. Active lymphocytic infiltration of the tumour suggests a good host response and a better prognosis. There are two histological variants, one with a more anaplastic appearance and another that is characterised by cells which closely resemble different phases of maturing spermatogonia (spermatocytic seminoma).

Seminomas metastasise mainly via the lymphatics (Figure 79.15) and haematogenous spread is uncommon. The lymphatic drainage of the testes is to the para-aortic lymph nodes near the origin of the gonadal vessels. The contralateral para-aortic lymph nodes are sometimes involved by tumour spread, but the inguinal lymph nodes are affected only if the scrotal skin is involved.

**Non-seminomatous germ cell tumours (NSGCT)**

These tumours may be tiny but can reach the size of a coconut. The smaller tumours may not even distort the tunica albuginea (Figure 79.16). The usual type of teratoma is yellowish in colour with cystic spaces containing gelatinous fluid (Figure 79.17). There are a number of histological types of non-seminomatous germ cell tumours (NSGCT), which may coexist within a single tumour:

- **Embryonal carcinoma.** Highly malignant tumours that occasionally invade cord structures.
- **Yolk sac tumour.** Tumours with this component secrete alpha fetoprotein (AFP).
- **Choriocarcinoma.** Often produces human chorionic gonadotrophin (HCG). This is a highly malignant tumour that metastasizes early via both the lymphatics and the bloodstream.
- **Teratoma.** These tumours contain more than one cell type with components derived from ectoderm, endoderm, and mesoderm. Tumours may range from ‘mature’ with
well-differentiated tissue elements to ‘immature’ with undifferentiated primitive tissues. All can metastasise.

**Interstitial cell tumours**

Interstitial cell tumours arise from Leydig or Sertoli cells. A Leydig cell tumour masculinises; a Sertoli cell tumour feminises. They are typically small well circumscribed tumours with a yellow cut surface. Microscopically, the cells are usually uniform and closely packed. Approximately 10 per cent are malignant.

Most prepubertal tumours (which account for around 25 per cent of cases) produce androgens, which cause sexual precocity including prominent external genitalia, suprapubic hair growth and a deep masculinised voice. Regression of the symptoms after orchidectomy may be incomplete. Most post-pubertal interstitial cell tumours produce feminising hormones leading to gynaecomastia, erectile dysfunction, loss of libido and azoospermia.

**Clinical features**

Usually the patient presents with a painless testicular lump. A sensation of heaviness can occur if the testis is two or three times its normal size, but only a minority of patients experience pain. In a few cases, an episode of trauma calls attention to the swelling. Some cases may simulate epididymo-orchitis and rarely some patients present with severe pain and acute enlargement of the testis because of haemorrhage into the tumour. Such cases can occasionally mimic testicular torsion.

Rarerly, the predominant symptoms are those of metastatic disease. Intra-abdominal disease may cause abdominal or lumbar pain and the mass may be discovered in the epigastrium. Lung metastases are usually silent but they can cause chest pain, dyspnoea and haemoptysis in the later stages of the disease. The primary tumour may not have been noticed by the patient, and indeed may be so tiny that it can be detected only by ultrasonography (Figure 79.16).

On examination, there is an intratesticular solid mass. If present, a lax secondary hydrocele does not usually obscure the underlying tumour. The epididymis becomes more difficult to feel when it is flattened or incorporated in the growth. The vas is never thickened and rectal examination is normal. Around 5 per cent of cases have gynaecomastia (mainly the NSGCT). Metastatic disease is rarely apparent clinically and is more usually identified by formal staging investigations. In 1–2 per cent of cases, the tumour is bilateral at the time of diagnosis.

**Investigation and staging**

The diagnosis is confirmed by ultrasound scanning of the testis (Figure 79.18) which is also able to assess the contralateral testis. It is a mandatory test in all suspected cases of testicular tumour.

In confirmed cases, staging is an essential step in planning treatment. Blood is taken prior to orchidectomy to measure the levels of tumour markers which are raised in around 50 per cent of cases. A rise in AFP is seen in around 50–70 per cent
of NSGCTs and a rise in HCG is seen in 40–60 per cent of NSGCTs and around 30 per cent of seminomas. When raised, these markers are used to monitor the response to treatment. The mean serum half-lives of AFP and HCG are 5–7 days and 2–3 days, respectively, and reassessment of the markers following orchidectomy can indicate whether all the tumour tissue has been removed.

While a chest x-ray will occasionally demonstrate the ‘classical’ cannon ball metastases (Figure 79.19), computed tomography (CT) of chest and abdomen has taken over as the most useful means of detecting metastatic disease and for monitoring the response to therapy. Such imaging is usually undertaken after the affected testis has been removed.

**Staging of testicular tumours**

While TNM staging is the most widely used system for the staging of testicular cancer, the older staging system of stages I–IV is still considered valuable in determining the treatment options:

The stages are:

- Stage I: the tumour is confined to the testis;
- Stage II: nodal disease is present but is confined to nodes below the diaphragm;
- Stage III: nodal disease is present above the diaphragm;
- Stage IV: nonlymphatic metastatic disease (most typically within the lungs) (Summary box 79.9).

**Summary box 79.9**

**Testicular tumours**

- A solid testicular lump that cannot be felt separately from the testis may be a malignant tumour
- Lymphatic spread is to the para-aortic lymph nodes
- Ultrasound is a mandatory investigation in all cases of suspected testicular tumour
- Tumour markers (AFP and HCG) should be measured prior to orchidectomy

**Treatment**

Scrotal exploration and orchidectomy for suspected testicular tumour

The orchidectomy is undertaken via an inguinal incision. The spermatic cord is displayed by dividing the external oblique aponeurosis and a soft clamp is placed across the cord to stop dissemination of malignant cells as the testis is mobilised into the wound. If necessary, the testis should be bisected along its anterior convexity to examine its internal structure. If there is a tumour, the cord should be double transfixed and divided at the level of the internal inguinal ring and the testis removed.

Management by staging and histological diagnosis (after orchidectomy)

The treatment of patients with testicular tumours is usually successful, even in cases that are advanced at presentation. This largely reflects the excellent response of these tumours to platinum-based chemotherapy and (for seminomatous tumours) to radiotherapy. Indeed in recent years the emphasis of clinical trials has been focused upon the identification of those patients who do not need chemotherapy, and who therefore will escape the side effects of treatment.

Stage I tumours

Seminomas are radiosensitive and for many years adjuvant radiotherapy to the para-aortic nodes was the mainstay of treatment for stage I disease. Some years ago, the excellent response to platinum-based chemotherapy led to chemotherapy being introduced for most men with stage I seminoma. However, current practice uses CT and tumour marker-based surveillance protocols with chemotherapy being reserved for men who demonstrate relapse.

NSGCTs are not radiosensitive, but they are highly sensitive to combination chemotherapy with bleomycin, etoposide and cis-platinum (so called BEP chemotherapy). Some good prognosis NSGCTs can be managed by surveillance protocols (using regular CT scanning and tumour marker measurement) with the more high risk cases receiving chemotherapy.
Stage II–IV tumours
Combination BEP chemotherapy is the mainstay of treatment for stages II–IV seminoma and NSGCT. Retroperitoneal lymph node dissection is sometimes needed in some cases of NSGCT when retroperitoneal masses remain after chemotherapy (Figure 79.20). The tissue removed may contain only necrotic tissue, but some patients have foci of mature teratoma or active malignancy. The operation can be formidable if the tumour mass is large, and retrograde ejaculation is likely unless steps are taken to preserve the sympathetic outflow to the bladder neck.

Prognosis
The prognosis of testicular tumours depends on several factors including the histological type and the stage at presentation. For seminoma, if there are no metastases, 90–95 per cent of patients will be alive five years after diagnosis. If there are poor prognostic features, the survival rate drops to around 70 per cent. For NSGCT, a five-year survival rate of more than 90 per cent is achievable in patients with good prognosis tumours while for more advanced tumours the five-year survival rate is about 60 per cent (Summary box 79.10).

Summary box 79.10
Testis tumour staging and treatment
- Tumour markers help to make the diagnosis and to follow the response to treatment
- CT scanning of chest and abdomen is central to the staging of testicular tumours
- Testicular tumours are extremely sensitive to platinum-based chemotherapy
- Prognosis is excellent when the patient is treated with combination chemotherapy in a cancer centre

TESTICULAR TUMOURS IN CHILDREN
These are usually anaplastic teratomas. They occur before the age of three years and are often rapidly fatal.

Figure 79.20 Computed tomography scan showing a large residual retroperitoneal mass after chemotherapy.

TUMOURS OF THE EPIDIDYMIS
These may be benign mesothelioma or malignant sarcoma or secondary carcinoma. They are extremely rare but should not be forgotten when the patient presents with a non-cystic lump in the epididymis.

THE SCROTUM

Fournier’s gangrene
Fournier’s gangrene is an uncommon and nasty condition (Figure 79.21) of infective origin that is characterised by sudden scrotal inflammation, with rapid onset of gangrene leading to exposure of the scrotal contents. Although it can occur in conjunction with sepsis of the testis, epididymis or perianal region, an obvious cause is absent in over half the cases. It can arise following minor injuries or procedures in the perineal area, such as a bruise, scratch, urethral dilatation, injection of haemorrhoids or opening of a periurethral abscess. Many patients have concurrent illnesses that diminish their defences, most notably diabetes mellitus and alcoholism.

There is a mixed infection of aerobic and anaerobic bacteria in a fulminating inflammation of the subcutaneous tissues, which results in an obliterative arteritis of the arterioles to the scrotal skin which in turn results in gangrene. The condition can spread rapidly to involve the fascia and skin of the penis, perineum and abdominal wall.

Clinical features
There is sudden pain in the scrotum associated with prostration, pallor and pyrexia. Cellulitis spreads rapidly (within hours) and progresses to necrosis until the entire scrotal and penile coverings slough, leaving the testes exposed but healthy.

Treatment
Treatment of a case of Fournier’s gangrene is a surgical emergency. Urgent wide surgical excision of the dead and infected tissue is essential. This should be accompanied by intravenous antibiotics. Supportive care is essential, because the patients often become severely septic. Early review of the wounds is helpful to confirm that all dead tissue has been removed, and if the patient survives the acute episode, skin grafting is often necessary. Despite best therapy, mortality rates as high as 50 per cent are often reported (Summary box 79.11).

Summary box 79.11

Fournier’s gangrene
- Fournier’s gangrene requires early and aggressive treatment if the patient is to survive
- Treatment involves urgent surgical debridement of necrotic tissue in combination with intravenous antibiotics

Filarial elephantiasis of the scrotum
Filarial elephantiasis of the scrotum is caused by obstruction of the pelvic lymphatics by worms of which Wuchereria bancrofti accounts for 90 per cent of cases. The condition is common in the tropics and is transmitted by mosquitoes. It is often
accompanied by superadded infection and lymphangitis, resulting in swelling of the genital skin and skin of the lower limbs. In longstanding cases, the enormously swollen scrotum may bury the penis (Figure 79.22). Associated symptoms and signs include fever, epididymitis, hydrocele and chyluria. The diagnosis is usually made clinically, although immunological testing can be helpful.

Medical treatment involves the use of diethylcarbamazine (DEC), ivermectin and albendazole, with the exact regime depending upon geographical location. Surgical treatment is rarely helpful, although a range of procedures has been devised to remove redundant skin and to reconstruct the enlarged scrotum.

**Non-filarial elephantiasis**

Elephantiasis can occur in the absence of filariasis, most notably in sub-Saharan Africa. Non-filarial elephantiasis can result from fibrosis of the lymphatics caused by lymphogranuloma venereum, but in many cases it is thought to arise as a consequence of persistent contact with irritant soils.

**Sebaceous cysts**

Sebaceous cysts are common in the scrotal skin. They are usually small and multiple (Figure 79.23).

**Carcinoma of the scrotum**

Chimney sweeps cancer was the first reported occupational cancer (described by Percival Pott in 1775). It is a rare cancer that has also been seen in other workers who come into contact with oil and coal products. Animal studies suggest that aromatic cyclic hydrocarbons are the aetiological factor. Nowadays, this tumour is rarely associated with any obvious aetiological factor. Unlike carcinoma of the penis, carcinoma of the scrotum is almost unknown in India and Asiatic countries.

The growth starts as a wart or ulcer (Figure 79.24) and as it grows it may involve the testis. The tumour should be excised with a margin of healthy skin. The management of the inguinal nodes parallels the management of penile cancer and if nodal enlargement does not settle with antibiotics following treatment of the primary, then a bilateral groin dissection is indicated.

**MALE FACTOR INFERTILITY**

For couples of unknown fertility status, approximately 15 per cent are unable to achieve a pregnancy within one year. The inability to conceive may be due to female factor infertility, male factor infertility or a combination of these two factors and approximately 20 per cent of cases of infertility are caused entirely by the male factor.

**Aetiology**

The two main causes of male factor infertility are testicular causes and vasal or epididymal obstruction. A few cases reflect endocrinological abnormalities, such as hypogonadism or hyperprolactinaemia.
Testicular causes include chromosomal problems (e.g. Klinefelter’s syndrome), microdeletions of the Y chromosome, cryptorchidism, mumps orchitis, drugs and radiation damage. In most cases, however, the cause is unclear. In these cases, there may be reduced numbers of sperm in the ejaculate (oligozoospermia) or a complete absence of sperm in the ejaculate (azoospermia). Obstructive causes include congenital absence of the vasa (often in association with cystic fibrosis), surgical damage to the vasa, epididymitis and azoospermia is inevitable in these cases.

Assessment and investigation
Given the interplay between male and female factors, the man should not be investigated in isolation from his female partner. A careful history is the mainstay of the assessment with a careful search for aetiological factors. Physical examination is usually normal, but occasionally the testes may feel small (suggestive of a testicular cause), the vasa may be absent, there may be evidence of endocrine abnormalities (gynaecomastia or abnormal hair distribution) or there may be a varicocele. The relation of any varicocele to the infertility is controversial and treatment is not usually indicated.

The female should also be assessed. It is important to remember that female fertility declines from the age of 35 years in a way that is not true of men. The age of the female is therefore important and the regularity of menstruation should be confirmed either by temperature testing or by endocrinological testing.

The assessment of the male includes semen analysis, which should be tested within 2 hours of the semen being produced. Two or three samples should be tested. The volume of the ejaculate, the numbers of sperm, their motility and the percentage of abnormal or damaged sperm are all predictive of the male fertility. An endocrine screen should be performed including serum testosterone, prolactin, FSH and LH.

Treatment
Sperm counts of less than 20 million sperm per mL are defined as oligozoospermia. If there is a reversible cause, it should be treated. However, in many cases, some form of assisted conception is required.

Azoospermia (the complete absence of sperm from the ejaculate) is either due to obstruction of the pathway of spermatozoa from the testis to the ejaculatory ducts or due to severe testicular failure. In the latter, the serum FSH is typically raised, while in obstructive cases, the FSH is typically normal. If there is doubt as to the cause, then testicular biopsy is mandated to check for the presence of spermatogenesis combined with vasography to assess the presence and location of any obstructive lesion. If the site of the obstruction can be identified, it may be possible to perform a bypass operation. Unfortunately, even in the best hands, the results of epididymovasostomy are poor.

Assisted conception including in vitro fertilisation (IVF) and intracytoplasmic sperm injection (ICSI) has revolutionised the management of male factor infertility regardless of the cause of the problem. In ICSI, spermatozoa harvested from the ejaculate, by aspiration of the epididymis or even from testicular biopsy, can be injected in vitro into ova obtained from the mother. Embryos are then transferred into the mother’s uterus at the four- to six-cell stage (Summary box 79.12).

Vasectomy for sterilisation
Vasectomy for sterilisation is a common and effective contraceptive procedure. It should be undertaken only after the couple has been carefully counselled. Both partners need to know that the operation is performed to make the man permanently
sterile. They should be warned that normal contraceptive precautions should continue until the success of the operation is confirmed by semen analysis performed 12–16 weeks after surgery. They should also be warned of the possibility of spontaneous recanalisation, which may restore fertility unexpectedly and of the possibility of chronic testicular pain which may occur in up to 5 per cent of men.

Vasectomy is easily and painlessly performed under local anaesthetic. The vasa are delivered through tiny bilateral scrotal incisions or through a single midline scrotal incision. For medico-legal reasons, it is wise to remove a segment of each vas to prove that it has been successfully divided. Burying the cut ends or turning them back on themselves helps to prevent them rejoining.

Reversal of vasectomy may not restore fertility even if technically successful because of damage to the testis secondary to the vasectomy. Although patency rates of 80 per cent or more are commonly reported, successful fertility rates are much lower and diminish with increasing delay from the time of vasectomy (Summary box 79.13).

**Summary box 79.12**

**Male infertility**

- Atrophy of the testis is associated with raised levels of FSH in the blood
- Testicular biopsy will show whether azoospermia is a result of obstruction or failure of sperm production
- If spermatozoa can be harvested they can be used in ICSI with a fertility rate of around 30 per cent

**Summary box 79.13**

**Vasectomy**

Counselling before vasectomy should include mention that:

- The operation is not immediately effective and that contraceptive precautions should be continued until there have been two negative semen analyses
- The procedure should be considered irreversible
- Spontaneous recanalisation is rare, but can occur
- There is a risk of chronic scrotal pain postoperatively

**FURTHER READING**

ANATOMY

The female external genitalia are described as the vulva, which is bordered by the mons veneris anteriorly and the labiocrural folds posterolaterally. The introitus tends to be open in parous women, but otherwise appears closed by the apposing labia majora. The labia minora are folds of skin that fuse anteriorly to form the clitoris, which contains erectile tissue similar to the penis. The fourchette is the posterior part of the introitus, which must stretch considerably to allow the delivery of a baby.

The vagina is an elastic, distensible tube, approximately 10 cm long, passing upwards and backwards from the introitus. The cervix protrudes into the vault of the vagina, dividing it into anterior, posterior and lateral fornices. Pelvic structures can be felt in the posterior and lateral fornices on bimanual examination, as the vaginal vault sits just below the pouch of Douglas (the area at the bottom of the pelvic cavity bordered by the uterus anteriorly and rectum posteriorly). The urethra and bladder neck sit above the anterior wall of the vagina; the perineal body and rectum behind the posterior wall (Figure 80.1).

The uterus, consisting of a body and a cervix, is a pear-shaped structure that is flattened anteroposteriorly giving its cavity a flat, triangular shape. The uterus is supported partly by ligaments attached to the cervix (transverse cervical, pubocervical and uterosacral) consisting of condensed connective tissue. The cervix is a canal, approximately 2 cm long, connecting the external os, which can be seen on speculum examination, to the internal os, where the cervix enters the uterine cavity. The length of the uterine cavity, including the cervical canal, is approximately 6 cm in nulliparous women and approximately 8 cm in parous women. The walls of the uterus are 1–2 cm thick and composed of muscular tissue (myometrium). The uterine cavity is lined with endometrium, a tissue that undergoes cyclical changes in response to ovarian hormones (see below under Reproductive physiology).

At the uterine fundus, on either side, are the cornua by which the uterus is connected to each Fallopian tube. These are thin, muscular tubes, approximately 10 cm long, which connect the peritoneal and uterine cavities. They are divided into four parts: intramural, isthmus, ampulla and fimbriated opening, which pick up the oocyte following its release at the time of ovulation. The tubes are very narrow in the isthmic and intramural parts but they widen in the ampullary region. Each tube is contained within the upper part of the broad ligament, a fold of peritoneum on either side of the uterus, which also contains blood vessels and the round and ovarian ligaments. The fimbriated opening and part of the ampulla, however, are free and closely associated with the ovary on either side. The ovaries are flattened, ovoid structures, approximately 3–4 cm long, suspended from the back of the broad ligament on either side of the pelvis. The ovarian blood vessels are contained within the infundibulopelvic ligaments, which are continuations of the broad ligaments to the pelvic brim on either side.

LEARNING OBJECTIVES

To understand:
- Pelvic anatomy and reproductive physiology
- The common causes of vaginal bleeding and acute pain in early pregnancy

- The surgical management of acute pelvic inflammatory disease, endometriosis, uterine fibroids and ovarian tumours

---

Gabriele Falloppio (Falloppius), 1523–1563, Professor of Anatomy, Surgery and Botany, Padua, Italy.
The cervix is located in the centre of the bony cavity of the pelvis and the uterus can be pivoted around this point. It is usually angled forwards (anteverted) at approximately 90° relative to the vagina. It is usually freely mobile but filling of the bladder or changes in position may rotate it backwards. In some women, the uterus is retroverted, either because of weak ligaments or because the uterus becomes adherent as the result of a disease process such as endometriosis. The uterus may also be angled forward (anteriorly) relative to the cervix when anteverted or backwards (retroverted) when retroverted, in which case it can usually be felt in the pouch of Douglas on vaginal examination. The most common cause of an enlarged uterus, aside from pregnancy, is the presence of fibroids (benign tumours of the myometrium) growing inside or outside the uterus. When fibroids are present, the overall size of the uterus is described in terms of weeks of pregnancy as it expands forwards and upwards into the abdominal cavity with increasing gestational age.

**REPRODUCTIVE PHYSIOLOGY**

The menstrual cycle is under the control of circulating hormones produced within the hypothalamic–pituitary–ovarian axis. Thus, gonadotrophin-releasing hormone (GnRH) produced in the hypothalamus stimulates the pituitary to produce follicle stimulating hormone (FSH) and luteinising hormone (LH), which in turn controls how the ovary produces an oocyte on a monthly basis and also the hormones oestrogen and progesterone. These hormones have an effect on many structures in the body, but principally on the endometrium, which prepares itself to receive a fertilised egg during the course of the menstrual cycle. In the first half (proliferative or follicular phase) of the cycle, following menstruation, the endometrium starts to regrow or proliferate in response to oestrogen produced by the growing ovarian follicle. The endometrium becomes thick and spongy during this phase of the cycle, associated with considerable angiogenesis.

Ovulation occurs at mid-cycle, on approximately day 14 (day 1 of the cycle is defined as the first day of menstruation), following which the follicle is transformed into the corpus luteum. In the second half (secretory or luteal phase) of the cycle, the endometrium thickens even more in response to the hormone progesterone, produced by the corpus luteum (Figure 80.2). If fertilisation occurs, the fertilised egg is transported along a Fallopian tube into the uterine cavity and then implants in the endometrium. If fertilisation does not occur or if the fertilised egg fails to implant, the endometrium is shed and menstruation occurs. Bleeding (a ‘period’) tends to last for 4 days, but can range from 2–6 days. Typically, about 40 mL of blood is lost during each period; if the bleeding is heavy (i.e. greater than 80 mL), blood clots may form. The whole process then starts again in the next menstrual cycle.

If fertilisation does occur, the duration of the pregnancy (gestational age) is traditionally calculated from the first day of the last menstrual period (LMP); however, ovulation may occur earlier or considerably later than day 14 or the woman’s recollection of the date of the LMP may be incorrect, which means that calculating gestational age on the basis of the LMP alone may be inaccurate. This explains the alternative practice of calculating gestational age using ultrasound measurements of fetal size.

**VAGINAL BLEEDING IN EARLY PREGNANCY**

A miscarriage is defined as the spontaneous loss of an intrauterine pregnancy at less than 24 weeks’ gestation. A miscarriage usually starts with painless vaginal bleeding, at which point it is defined as a threatened miscarriage. The bleeding may then become heavier with associated uterine cramps, at which point it becomes an inevitable miscarriage. Blood clots and products of conception (i.e. fetal and placental tissue) are passed through the cervical os until the uterus is emptied (defined as a complete miscarriage). Sometimes, not all the products of conception are passed spontaneously (defined as an incomplete miscarriage) and the woman may require an evacuation of retained products of conception (ERPC) to remove what is left of the pregnancy. The operation involves passing a plastic suction curette through the cervix into the uterine cavity. The current (2006) Royal College of Obstetricians and Gynaecologists (RCOG) recommendations are for ERPC to be considered if there is persistent excessive bleeding, haemodynamic instability, evidence of infected retained tissue or suspected gestational trophoblastic disease. Serious operative complications, which are fortunately rare, include uterine perforation with, possibly, intra-abdominal trauma (e.g. bowel damage), cervical tears and haemorrhage.

In the case of a miscarriage, on vaginal examination there is typically no cervical excitation (pain on moving the cervix) or tenderness in the vaginal fornices, which are signs associated with an ectopic pregnancy. The uterus feels the right size or smaller for the gestational age. The internal cervical os, by definition, is closed if the miscarriage is threatened or complete and open if the miscarriage is inevitable or incomplete. If the fetus has not developed (defined as a missed abortion) the uterus will feel small for the gestational age and there may have been no bleeding, in which case the os will be closed. In such circumstances, the os will need to be dilated before performing the ERPC.

An ultrasound scan is usually performed to determine whether there is a viable intrauterine pregnancy present. It may not be possible to determine the precise location of the pregnancy because the woman has had a complete miscarriage, the pregnancy is not sufficiently advanced or she has an ectopic pregnancy that is not visible on ultrasound. For these reasons, it is important to establish the gestational age as accurately as possible, on the basis of the LMP and the length/regularity of the menstrual cycle, as well as with any other relevant information, e.g. fertility treatment. It is still not uncommon, especially in
early pregnancy, to make the diagnosis of a miscarriage on clinical grounds alone, for example in the case of:

- heavy vaginal bleeding with clots and associated uterine cramps;
- no history of abdominal pain;
- no cervical excitation or tenderness in the vaginal fornices;
- no risk factors for an ectopic pregnancy, e.g. a past history of pelvic inflammatory disease (PID) or previous tubal surgery.

Vaginal bleeding in early pregnancy may also result from a local cause such as a cervical lesion (which may first manifest as bleeding after intercourse) or, rarely, trauma.

**VAGINAL BLEEDING IN THE NON-PREGNANT STATE**

Bleeding in the non-pregnant state may occur at the time of an expected menstrual period, between periods (intermenstrual bleeding) or after intercourse (post-coital bleeding). It may also occur after surgical instrumentation of the uterus and/or cervix, including insertion of an intrauterine contraceptive device (IUCD). The principal causes of these types of bleeding are shown in Table 80.1.

The mainstay of management is to identify and treat pathology (except in women <40 years old with heavy, menstrual periods in whom pathology is very rarely found; these women tend to be treated symptomatically). This usually involves ultrasound examination and an endometrial biopsy, either under direct vision at hysteroscopy or blindly with a Pipelle. The indications for endometrial biopsy are shown in Summary box 80.1.

### Summary box 80.1

**Indications for endometrial biopsy**

Endometrial biopsy should be considered in the following women:

- All women >40 years old with excessively heavy, irregular or frequent bleeding
- Younger women with major risk factors for endometrial hyperplasia/cancer:
  - Polycystic ovarian syndrome
  - Obesity
  - Tamoxifen treatment
- Unopposed oestrogen therapy
- Family history of endometrial/colon cancer, especially hereditary non-polyposis colorectal cancer (Lynch syndrome)
- Younger women who fail to respond to conventional treatment

Women taking tamoxifen – the selective oestrogen receptor modulator used in breast cancer treatment – represent a special group because the drug can induce endometrial polyps, hyperplasia, cancer and, rarely, uterine sarcomas, which are much more aggressive. Tamoxifen treatment results in a doubling of the risk of endometrial cancer after one to two years of treatment and a quadrupling after five years. The relationship is time-dependent and dose-independent and the risk does not decrease after stopping treatment. There is no clear consensus regarding the need for screening and which method to use; the alternative, more common, approach is to investigate only those women who develop post-menopausal bleeding with tamoxifen use. Aromatase inhibitors such as anastrozole, letrozole and exemestane, which are also used in the treatment of breast cancer but whose effects are not mediated via the oestrogen receptor, are associated with less endometrial pathology than tamoxifen and it has even been suggested that aromatase inhibitors may reverse abnormalities induced by tamoxifen.

Women with hereditary non-polyposis colorectal cancer (HNPCC) (Lynch syndrome) and those who are at high risk of developing HNPCC are another special group, as the lifetime risk of developing endometrial cancer is as high as 60 per cent. Unlike sporadic cases of endometrial cancer, which are usually diagnosed during the sixth and seventh decades, the mean age at diagnosis in HNPCC patients is the fifth decade. However, it appears that five-year survival rates in HNPCC patients with endometrial cancer are similar to those in women with sporadic disease. International guidelines suggest that these women should be screened annually from the age of 35 years with transvaginal ultrasound, to measure endometrial thickness and look for polyps, and with endometrial biopsy.

Menstrual bleeding may be excessively heavy, irregular or frequent in the absence of pathology; this is known as dysfunctional uterine bleeding. Medical treatments used to reduce the amount of menstrual loss include tranexamic acid, mefenamic acid and the combined oral contraceptive (COC). It may be necessary to stop the bleeding completely using high-dose progestagens, the COC taken continuously or a GnRH agonist, which induces a menopause-like state. Increasingly, an intrauterine system (IUS) similar to a conventional coil, which releases levonorgestrel, is offered to patients as an alternative; it has the added advantage of being a reliable contraceptive.

The surgical treatments for excessive bleeding and their principal operative complications are described in Table 80.2; they are divided into those procedures that retain the uterus and those that do not. The ovaries may or may not be removed at the same time depending upon the woman’s age and any coexisting pathology. The aim of all of the ablation methods is to reduce menstrual bleeding by ablating the endometrial layer and some of the underlying myometrium using electrical, thermal or laser energy. Amenorrhoea is not guaranteed, but the procedures are less invasive and costly than hysterectomy. Clearly, none of these surgical treatments is suitable for women who wish to conceive.

Abnormal bleeding can also be caused by invasive carcinoma of the cervix, the incidence of which has been reduced by screening programmes that aim to detect the precancerous state – cervical intraepithelial neoplasia (CIN) – using cervical cytology. In the UK, this is carried out every three to five years in women.
aged between 25 and 65 years. Infection with certain human papillomavirus (HPV) serotypes (16, 18, 31 and 33) is associated with an increased risk of invasive disease. Abnormalities in cervical cytology are followed up by microscopic examination of the cervix (colposcopy). CIN may be treated with local ablation (cryocautery, cold coagulation, electrodiathermy or laser) or excision (large loop excision of the transformation zone (LLETZ)). However, it is very likely that the incidence of CIN will decrease steadily in the future as a result of vaccination against HPV in young girls and HPV testing.

**ACUTE PELVIC PAIN IN EARLY PREGNANCY**

**Ectopic pregnancy**

An ectopic pregnancy is one that grows outside the uterine cavity, almost always in a Fallopian tube (rare sites include the ovary, cervix and broad ligament). As the ectopic grows, the placenta infiltrates blood vessels within the Fallopian tube, which can cause bleeding within the tube and bleeding into the peritoneal cavity. Further growth of the ectopic pregnancy can rupture the Fallopian tube causing substantial intraperitoneal blood loss. It is the most common cause of maternal death in the first trimester and accounts for 9 per cent of maternal deaths in the UK. The major risk factors for ectopic pregnancy are shown in Summary box 80.2.

**Summary box 80.2**

**Risk factors for ectopic pregnancy**
- Previous pelvic inflammatory disease
- Smoking
- Older age
- Previous spontaneous miscarriage
- Previous medical termination
- History of infertility
- Previous use of an intrauterine contraceptive device

An ectopic pregnancy may be suspected on clinical grounds, but making the diagnosis can be difficult because the presentation is so variable and can mimic that of a miscarriage (Summary box 80.3).

**Summary box 80.3**

**Differential diagnoses for acute pain in early pregnancy**
- Ectopic pregnancy
- Miscarriage
- Urinary tract infection
- Ovarian accident
- Pain unrelated to pregnancy, e.g. acute appendicitis

There may be a history of lower abdominal pain with a small amount of vaginal bleeding at 4–6 weeks’ gestation. On vaginal examination, there may be cervical excitation and tenderness in the vaginal fornices; the cervical os is closed. Alternatively, the woman may not have any symptoms or physical findings. The urinary pregnancy test is usually positive. Modern monoclonal antibody-based urine tests can detect the beta subunit of human chorionic gonadotropin (β-hCG) at levels of 25 IU/L, which are reached 9 days post-conception, i.e. on day 23 of the menstrual cycle assuming ovulation occurred on day 14.

A transvaginal ultrasound scan should be performed if the diagnosis is suspected. The complete absence of an intrauterine gestational sac with a positive pregnancy test increases the probability of an ectopic pregnancy unless the pregnancy is not sufficiently advanced for the sac to be seen on ultrasound in the uterus. An ectopic pregnancy is more likely if fluid is seen in the pelvis or an adnexal mass is seen on ultrasound.

In equivocal cases, measuring serum levels of β-hCG can help to establish the diagnosis. β-hCG levels double every 48 hours if the pregnancy is viable and intrauterine. Levels tend to be static or the rise is less than double over a 48-hour period if the pregnancy is ectopic. A single level above approximately 1500 IU/L in association with an empty uterus on ultrasound is highly suggestive of an ectopic pregnancy. The best diagnostic test is laparoscopy (Figure 80.3); occasionally, however, if the pregnancy is not sufficiently advanced, the ectopic pregnancy is too small to be seen in the Fallopian tube. There is also a view that a laparoscopy should only be performed once a miscarriage has been excluded because of the surgical and anaesthetic risks associated with the procedure.

Figure 80.3 Laparoscopy showing an ectopic pregnancy.

Once an ectopic pregnancy has been diagnosed at laparoscopy, a salpingectomy is usually performed. A salpingostomy may be performed instead as some gynaecologists maintain that subsequent intrauterine pregnancy rates are higher and recurrent ectopic rates lower following conservative surgery. Laparoscopy is the preferred approach because it is associated with shorter operation times, less intraoperative blood loss, shorter hospital stays and similar subsequent intrauterine pregnancy rates.

In practice, the type of operation chosen depends on factors such as the following:

- **The amount of bleeding.** An immediate laparotomy may be required if the woman has lost a great deal of blood.
is an intracellular organism; therefore, cervical excitation and adnexal tenderness; Previous ectopic pregnancy or tubal surgery. One usually tries to be as conservative as possible if the other tube has been affected by PID (i.e. it is closed or densely adherent to other pelvic organs).

- The state of the tube, i.e. the size of the ectopic pregnancy and whether or not it has ruptured (in general, if the ectopic pregnancy is too large the chances of conservative surgery being successful are small; if it has ruptured, there is little point in trying to be conservative).

- The state of the other tube. One usually tries to be as conservative as possible if the other tube has been affected by PID (i.e. it is closed or densely adherent to other pelvic organs).

- Previous ectopic pregnancy or tubal surgery. One usually performs a salpingectomy if a woman has had a previous ectopic pregnancy or tubal surgery in the same tube.

- The woman’s fertility intentions. One usually performs a salpingectomy if a woman does not want more children.

Sometimes, the ectopic pregnancy is located at the very end of the tube, in which case it may be possible simply to ‘milk’ it out, thereby conserving the tube. The principal disadvantage of this method (and salpingostomy) is that some residual trophoblastic tissue can be left inside the tube. The tissue often survives and continues to grow, which can cause intra-abdominal bleeding. The best method for determining whether all of the tissue has been removed at surgery is to measure serial serum β-hCG levels, which should fall to zero over time if all the tissue has been removed; β-hCG levels remain constant or rise if there is residual trophoblastic tissue, which may necessitate another laparoscopy to remove the tube.

In the United States, many women avoid surgery altogether by being treated with intramuscular injections of methotrexate, which is toxic to trophoblastic tissue. The drug has some side effects and the treatment carries the risks associated with residual trophoblastic tissue, namely internal bleeding and the eventual need for a laparoscopy. In the UK, methotrexate seems to be used only in those patients who are at increased surgical risk (e.g. the morbidly obese or those with extensive pelvic adhesions).

After treatment, the patient who still has one or both tubes should be warned that she is at increased risk of another ectopic pregnancy. She should therefore be encouraged to present as early as possible in a subsequent pregnancy to rule out this diagnosis.

**INFECTION**

The overwhelming majority of cases of acute PID are caused by ascending infection, which is usually sexually transmitted. Rarer causes include spread from other pelvic organs, e.g. the appendix. *Chlamydia trachomatis* is the most common organism responsible for PID; the prevalence of *Neisseria gonorrhoeae* varies depending upon the locality. Infection involves the upper genital tract, particularly the endometrium and Fallopian tubes. Risk factors include young age at first sexual activity, a high number of sexual partners and current use of an IUCD; infection may also follow a surgical procedure, e.g. termination of pregnancy.

There are no definitive criteria for the diagnosis of acute PID. Most clinicians rely instead upon the presence of one or more of the following features, which are suggestive of the diagnosis:

- lower abdominal pain and tenderness;
- deep dyspareunia (pain on intercourse);
- abnormal vaginal or cervical discharge;
- cervical excitation and adnexal tenderness;
- fever >38°C.

The differential diagnoses include endometriosis, urinary tract infection, appendicitis and gastrointestinal dysfunction. A raised neutrophil count and an elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) level support the diagnosis. Ultrasound may be useful if there appear to be hydrosalpinx present and/or tubo-ovarian abscesses. All women with suspected PID should be screened for *N. gonorrhoeae* and *C. trachomatis* by taking endocervical with or without urethral swabs. *C. trachomatis* is an intracellular organism; therefore, samples obtained for diagnostic purposes should contain cellular material. It is important to wipe off any discharge before inserting the swab inside the cervical os and firmly rotating it against the endocervix.

The current RCOG (2008) guidelines recommend a low threshold for empirical treatment because the consequences of failing to treat acute PID effectively are so significant. Treatment should commence as soon as samples have been obtained for culture even though the results are unavailable; it should include a broad-spectrum antibiotic against coliforms and anaerobic...
species, which are responsible for secondary infection. Contact tracing and treatment, if possible, are essential (Summary box 80.4).

Inadequate or inappropriate treatment is associated with a significant risk of developing infertility, ectopic pregnancy, Fitz-Hugh–Curtis syndrome (an extrapelvic manifestation of PID associated with right upper quadrant pain, which probably results from inflammation of the liver capsule and diaphragm) and chronic pelvic pain in the future. The risk of infertility is obviously of great concern. Approximately 20 per cent of women treated for PID will become infertile because of tubal damage; >50 per cent of tubal infertility cases are due to C. trachomatis although, interestingly, many of these women do not report a history of PID (Summary box 80.5). In total, 6 per cent of women will have an ectopic in the first pregnancy following an episode of acute PID, a figure that is approximately ten times greater than the rate in the general population.

**Summary box 80.4**

**Treatment of pelvic inflammatory disease**

- Because of the lack of definitive clinical diagnostic criteria, a low threshold for the empirical treatment of pelvic inflammatory disease (PID) is recommended.
- Women with suspected PID should be screened for gonorrhoea and Chlamydia. Testing for gonorrhoea should be with an endocervical specimen, tested via culture (direct inoculation on to a culture plate or transport of the swab to the laboratory within 24 hours) or using a nucleic acid amplification test (NAAT). Screening for Chlamydia should also be from the endocervix, preferably using a NAAT.
- Taking an additional sample from the urethra increases the diagnostic yield for gonorrhoea and Chlamydia. A first-catch urine sample provides an alternative sample.
- Outpatient antibiotic treatment should be commenced as soon as the diagnosis is suspected. Treatment should be based on one of the following regimens:
  - 400 mg oral ofloxacin twice a day plus 400 mg oral metronidazole twice a day for 14 days; or
  - 250 mg intramuscular ceftriaxone immediately or 2 g intramuscular cefoxitin immediately with 1 g oral probenecid, followed by 100 mg oral doxycycline twice a day plus 400 mg metronidazole twice a day for 14 days.
- Admission to hospital is appropriate in the following circumstances:
  - Surgical emergency cannot be excluded.
  - Clinically severe disease.
  - Tubo-ovarian abscess.
  - PID in pregnancy.
  - Lack of response to oral therapy.
  - Intolerance to oral therapy.
- In more severe cases, inpatient antibiotic treatment should be based on intravenous therapy, which should be continued until 24 hours after clinical improvement and followed by oral therapy. Recommended regimens are:
  - 2 g intravenous ceftriaxone three times a day plus 100 mg intravenous doxycycline twice a day (oral doxycycline may be used if tolerated), followed by 100 mg oral doxycycline twice a day plus 400 mg oral metronidazole twice a day for a total of 14 days; or
  - 900 mg intravenous clindamycin three times a day, plus intravenous gentamicin: 2 mg/kg loading dose followed by 1.5 mg/kg three times a day (a single daily dose of 7 mg/kg may be substituted), followed by 450 mg oral clindamycin four times a day to complete 14 days or 100 mg oral doxycycline twice a day plus 400 mg oral metronidazole twice a day to complete 14 days or 400 mg intravenous ofloxacin twice a day plus 500 mg intravenous metronidazole three times a day for 14 days.

**Summary box 80.5**

**Chlamydia and gonorrhoea testing**

There is a need to test women (especially those sexually active under the age of 25 years) who present with:

- Purulent vaginal discharge.
- Post-coital/intermenstrual bleeding.
- Mucopurulent cervicitis.
- Inflamed/friable cervix (which may bleed on contact).
- Urethritis.
- Suspected pelvic inflammatory disease.
- Reactive arthritis.

The majority of suspected cases are treated in the community, but hospital admission is advisable if there is doubt about the diagnosis or symptoms/signs are severe. In hospital, antibiotics should be given intravenously until 24 hours after clinical improvement. If there is an IUCD in situ, it should be removed with adequate counselling regarding pregnancy risk (if intercourse has occurred recently) and future contraception.

Severe PID manifests as a tubo-ovarian abscess, so named because the Fallopian tube and ovary become blended into a single, pus-filled, inflammatory mass, which is usually adherent to the uterus and surrounding bowel. The infection may have
progressed from a milder form of PID or, increasingly, it may result from the introduction of infection or bowel damage at transvaginal oocyte aspiration in a patient undergoing in vitro fertilisation (IVF). Modern medical practice is to manage tubo-ovarian abscesses (Figure 80.4) conservatively unless the patient fails to respond to intravenous antibiotics and systemic support. The response is judged to be inadequate if the woman remains systemically unwell, her symptoms do not improve, fever is not reduced, the white blood cell count does not fall and there is no evidence on ultrasound of the abscess becoming smaller. In such circumstances, surgical treatment is necessary, i.e. adhesiolysis and drainage of the abscess, at laparotomy or laparoscopy. As most women with a tubo-ovarian abscess are in the reproductive years, the intention is always to be as conservative as possible at surgery. Rarely, however, if the abscess has ruptured (Figure 80.5) and the patient is extremely ill, then hysterectomy and bilateral salpingo-oophorectomy may be necessary.

Abscess drainage under radiological guidance, e.g. a transgluteal approach via the greater sciatic foramen under computed tomography (CT) guidance, is sometimes performed. Transvaginal ultrasound-guided aspiration has also been advocated. It is clearly less invasive and there are claims that the method is as effective as surgery; however, it carries additional risks such as bowel damage.

UTEROVAGINAL PROLAPSE

Congenital weakness of the pelvic floor ligaments and fascia may be found in conditions such as spina bifida and bladder extrophy. Far more common, however, are the acquired forms of pelvic floor damage caused by prolonged or difficult labour and multiparity. A gradual increase in denervation of the striated muscle of the pelvic floor with age and oestrogen deficiency at the menopause can also occur in nulliparous women (Figure 80.6).

A minor degree of prolapse may be asymptomatic but with more significant degrees the patient complains of ‘something coming down’. A cystocoele (bladder prolapse) and a cystourethrocele lead to the sensation of a lump in the vagina and may also be associated with incontinence and recurrent urinary infections. Uterine descent can lead to backache; with complete prolapse of the uterus (procidentia) there may be vaginal discharge, ulceration of the vaginal skin and bleeding. A rectocoele (prolapse of the rectum into the vagina) may cause difficulties with defaecation or a sensation of incomplete defaecation, which is relieved by digital reduction of the prolapse.

Non-surgical management of uterovaginal prolapse is with physiotherapy, hormone replacement therapy (HRT) and the use of vaginal rings and pessaries. The vinyl ring is inserted between the posterior fornix and the pubic bone. The main complication is vaginal ulceration and infection leading to discharge and bleeding; it is advisable, therefore, to replace the ring frequently. The aims of surgical management are usually to correct the prolapse, treat any associated incontinence and preserve coital function if appropriate. The surgical procedures are intended to restore the uterovaginal anatomy and position. They may be carried out using a vaginal or abdominal approach or increasingly by a laparoscopic or minimal access approach with the use of vaginal slings and tapes (Table 80.3).

The Manchester repair was introduced at St Mary’s Hospital for Women and Children, Manchester, UK.
**TUMOURS**

**Uterine fibroids (leiomyomas)**

Fibroids are benign, well-circumscribed, smooth muscle tumours of the uterus. Most women will have more than one fibroid, varying in diameter from 1–10 cm, which are typically found in the following locations (Figure 80.7):

- **Subserosal** may cause pressure symptoms (see below); if pedunculated, they can be difficult to distinguish from an ovarian tumour.
- **Intramural** may similarly cause pressure symptoms; associated with infertility and heavy periods.
- **Submucosal** associated with infertility, recurrent pregnancy loss and heavy periods; if pedunculated, may occasionally extrude through the cervical os.
- **Rare** sites include the broad ligament and cervix.

Women with uterine fibroids will present with heavy and/or irregular menstrual bleeding, pressure symptoms or problems conceiving, especially if there is a fibroid in the uterine cavity. The pressure symptoms include pelvic discomfort, urinary incontinence, frequency and retention, constipation and backache. When large fibroids are present, back pressure may cause or exacerbate varicosities. Although these symptoms are common, it is important to note that some women with fibroids are asymptomatic. Rarely, women may present acutely with pain arising from torsion of a pedunculated fibroid or red degeneration, especially in pregnancy.

The diagnosis is usually apparent on bimanual and/or abdominal examination, on the basis of finding an enlarged uterus with attached swellings. The principal differential diagnosis is an ovarian tumour; as a general rule, the uterus is felt separately on vaginal examination if an ovarian tumour is present, although not if the structures are adherent to each other. Ultrasound can
usually distinguish fibroids from ovarian tumours; if not, magnetic resonance imaging (MRI) is clinically useful (Figure 80.8) but, sometimes, it may be necessary to perform a laparoscopy to distinguish between the two pathologies (Figure 80.9).

Emergency surgical treatment is only required if there is substantial menstrual bleeding or uncontrollable pain; these are rare events. Otherwise, the woman has time to consider her treatment options, which include shrinkage of the fibroids by inducing a hypo-oestrogenic state with a GnRH agonist, uterine artery embolisation (UAE), myomectomy (removal of the individual fibroids) and hysterectomy. The choice depends upon the woman’s age and fertility intentions, the size and number of fibroids and their location. It is also important to know whether there are fibroids in the uterine cavity, especially if the woman is trying to conceive.

A GnRH agonist will usually shrink fibroids, but this class of drug has the disadvantage that treatment cannot be continued indefinitely because of the associated loss in bone mineral density; in addition, the fibroids tend to regrow to their original size when treatment is discontinued. UAE is becoming increasingly popular as an alternative to surgery. It involves blocking the blood supply to the fibroids using a technique in which particles are embolised into each uterine artery via an angiographic catheter in a similar manner to the well-established technique for treating massive post-partum haemorrhage (Figure 80.10). Following embolisation, the fibroids usually shrink, bringing symptomatic relief, i.e. decreased menstrual bleeding and fewer pressure symptoms. Complications include arterial injury at the site of catheter insertion, severe pain as a result of uterine ischaemia, infection, and ovarian damage and thromboembolism (a small number of deaths have been reported from uterine infection and pulmonary embolism). There is no consensus regarding the suitability of the technique for women who wish to conceive. Numerous pregnancies have been reported in women who have had UAE, but concern still exists regarding the possible adverse effects on myometrial strength and ovarian function, which

might affect a woman's chances of conceiving, carrying the pregnancy and delivering normally.

Myomectomy (performed at laparotomy or increasingly at laparoscopy) involves the removal of pedunculated, subserosal and/or intramural fibroids and closure of any defects left in the uterine wall. Surgical complications are unusual; in exceptional circumstances, however, a hysterectomy may be necessary because of uncontrollable blood loss. Fibroids in the uterine cavity should be removed hysteroscopically; the risks of the procedure are similar to those for transcervical resection of the endometrium (TCRE) (see Table 80.2).

Endometriosis
Endometriosis – defined as the presence of endometrial-like tissue in extrauterine sites – is a complex genetic trait that affects up to 10 per cent of women in the reproductive years. The symptoms associated with the disease include severe dysmenorrhoea, chronic pelvic pain, ovulation pain, deep dyspareunia, cyclical symptoms related to the involvement of other organs (e.g. bowel or bladder) with or without abnormal bleeding, infertility and chronic fatigue. However, the predictive value of any one symptom or set of symptoms remains uncertain as each can have other causes (e.g. irritable bowel syndrome or interstitial cystitis) and a significant proportion of affected women are asymptomatic.

The most commonly affected sites are the pelvic organs and peritoneum, although distant sites such as the lungs are occasionally affected (resulting in symptoms such as recurrent haemoptysis at the time of menstruation). The extent of the disease varies from a few, small lesions on otherwise normal pelvic organs to large, ovarian, endometriotic cysts (endometriomas). There can be extensive fibrosis in structures such as the uterosacral ligaments (Figure 80.11) and adhesion formation causing marked distortion of pelvic anatomy (Figure 80.12). Disease severity can be assessed simply by describing the operative findings or, quantitatively, using various classification systems, but there is little correlation between such systems and the type or severity of pain symptoms.

Endometriosis typically appears as superficial ‘powder-burn’ or ‘gunshot’ lesions on the ovaries, serosal surfaces and peritoneum – black, dark-brown or bluish puckered lesions, nodules or small cysts containing old haemorrhage surrounded by a variable extent of fibrosis (Figure 80.13). Atypical or ‘subtle’ lesions are also common, including red implants (petechial, vesicular, polypoid, haemorrhagic, red flame-like) and serous or clear vesicles. Other appearances include white plaques or scarring and yellow-brown peritoneal discoloration of the peritoneum.

Ovarian endometriomas usually contain thick fluid like tar. They are distinguishable from simple haemorrhagic ovarian cysts because, typically, they are densely adherent to the peritoneum of the ovarian fossa. The surrounding fibrosis may involve the bowel. Deeply infiltrating endometriotic nodules represent another disease type. They extend more than 5 mm beneath the peritoneum and may grow into the uterosacral ligaments, vagina, bowel, bladder or ureters; when such lesions grow into the vagina, they may be visible on speculum examination as ‘blue-domed’ cystic lesions in the posterior fornix. Lesions infiltrating the bowel may mimic cancer in their presentation.

The diagnosis of endometriosis is usually made on visual inspection of the pelvis at laparoscopy; non-invasive diagnostic tools, such as ultrasound scanning, can reliably detect only severe forms of the disease, i.e. endometriomas. The treatment options are limited because the cause is uncertain; these include hormonal drugs to suppress ovarian function, the levonorgestrel-IUS and surgical ablation of endometriotic lesions. Women may require multiple admissions for surgery and/or prolonged treatment with costly drugs that have problematic side effects. Lastly, patients with endometriosis may be at increased risk of ovarian cancer (especially endometrioid and clear-cell types) and non-Hodgkin’s lymphoma, which adds to the burden of the disease.

Finding pelvic tenderness, a fixed retroverted uterus, tender uterosacral ligaments or enlarged ovaries on examination is suggestive of endometriosis. The diagnosis is more certain if deeply infiltrating nodules are found on the uterosacral ligaments or in the pouch of Douglas and/or visible lesions are seen in the vagina or on the cervix. The findings may, however, be normal.

For a woman who has completed her family, hysterectomy plus bilateral salpingo-oophorectomy and removal of all the...
endometriosis present offers a good chance of cure. However, surgical treatment in a woman who wishes to conceive in the future aims to be as conservative as possible, ensuring in particular that ovarian function is preserved. The aim is to remove all of the endometriotic tissue and restore uterine and tubal patency by lysing adhesions. The standard (preferably laparoscopic) methods used are ovarian cystectomy and tissue excision or ablation with electrodiathermy, thermal coagulation or laser. The surgical risks include those for any laparoscopic procedure, as well as damage to the ureters and bowel; the risks are increased if deeply infiltrating disease is present, particularly if there is bowel wall involvement. Rarely, infection in an endometrioma will result in the formation of a tubo-ovarian abscess.

**Benign ovarian tumour and cysts**

Overall, 90 per cent of ovarian tumours are benign, although there is an increased risk of malignancy in older women. Ovarian tumours are subdivided into five main categories according to the World Health Organization’s classification system (Table 80.4).

<table>
<thead>
<tr>
<th>Classification of ovarian tumours.</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Epithelial tumours</td>
<td>Represent about 75% of all ovarian tumours and 90–95% of ovarian malignancies</td>

<tr>
<td>Sex cord–stromal tumours</td>
<td>Represent about 5–10% of all ovarian neoplasms</td>
</tr>
<tr>
<td>Germ cell tumours</td>
<td>Represent about 15–20% of all ovarian neoplasms</td>
</tr>
<tr>
<td>Metastatic tumours</td>
<td>Represent about 5% of ovarian malignancies; usually arise from breast, colon, endometrium, stomach and cervical cancers</td>
</tr>
<tr>
<td>Other</td>
<td>A small number of other types of neoplasms, which develop from ovarian soft tissue or non-neoplastic processes</td>
</tr>
</tbody>
</table>

The most common solid tumours in young women are cystic teratomas (known more commonly as dermoid cysts), which typically contain a variety of tissues including hair, teeth and bone. Benign ovarian tumours are often asymptomatic and may present coincidentally, for example when an abdominal radiograph reveals the appearance of a tooth in the abdomen or pelvis. Conversely, they may present with pain, abdominal swelling and pressure effects. The pain may be the result of torsion or bleeding inside the cysts. Management will depend, to some extent, on the age of the woman and the characteristics of the cyst. In older women, a conservative approach is reasonable only if the risks of malignancy are low (see Ovarian cancer). In younger women (<35 years), the cyst can be followed by serial ultrasound scanning as many will regress – haemorrhagic corpus luteal cysts, for example, will often shrink after three to four months’ treatment with a COC. If there is uncontrollable pain, haemodynamic collapse or a suspicion of torsion, or the cyst does not regress, then laparoscopic ovarian cystectomy with conservation of ovarian tissue is the treatment of choice. As the vast majority of oocytes lie within 5 mm of the surface of the ovary, a carefully carried out cystectomy can leave a normally functioning ovary (Figure 80.14) (Summary box 80.6).

![Figure 80.13 Endometriosis seen on the peritoneal surface of the diaphragm.](image)

**Summary box 80.6**

**Management of benign ovarian cysts**

- Masses are usually detected incidentally but may be suggested by symptoms and signs
- A pregnancy test is done to exclude ectopic pregnancy
- Transvaginal ultrasonography can usually confirm the diagnosis. If results are indeterminate, magnetic resonance imaging or computed tomography scanning may help
- Masses with radiographic characteristics of cancer (e.g. cystic and solid components, surface excrescences, multilocular appearance, irregular shape) require removal
- Tumour markers may help in the diagnosis of specific tumours
- In women of reproductive age, simple, thin-walled cystic adnexal masses of 5–8 cm (usually follicular) without characteristics of cancer do not require further investigation unless they persist for more than three menstrual cycles
- Many ovarian cysts resolve without treatment; serial ultrasonography is carried out to document resolution. Cyst removal (ovarian cystectomy) via laparoscopy or laparotomy may be necessary for cysts ≥8 cm, cysts that persist for more than three menstrual cycles and haemorrhagic corpus luteum cysts with signs of peritonitis
- Cystic teratomas require removal via cystectomy if possible. Oophorectomy is carried out for fibromas, cystadenomas, cystic teratomas >10 cm and cysts that cannot be surgically removed from the ovary

**Ovarian cancer**

Ovarian cancer is the sixth most common malignancy among women worldwide and the leading gynaecological cause of death in the developing world. In the UK, over 6000 women die annually from ovarian cancer. Over 90 per cent of cancers arise from the surface epithelium of the ovary (which has the same embryological origins as the peritoneum); the majority are sporadic rather than inherited. The peak incidence is in the age range of 60–70 years. The overall five-year survival rate is less than 50 per...
cent because approximately two-thirds of women present with advanced disease. The usual presenting symptoms are:

- abdominal distension and/or pain;
- weight gain and increased girth (ascites);
- urinary obstruction.

However, over half of all women present initially to a specialty other than gynaecology, with often vague symptoms caused by metastatic disease, e.g., shortness of breath, gastrointestinal disturbance or a change in bowel habit. Consequently, it is important to include ovarian cancer in the differential diagnosis of any woman presenting with recent onset of persistent, nonspecific, abdominal symptoms (including those whose abdomen and pelvis appears normal on clinical examination).

Ultrasound is the first-line investigation if an ovarian mass is suspected on clinical grounds. The features suggestive of malignancy on ultrasound include the presence of:

- cyst complexity (number of locules, wall structure, thickness of septae, fluid echogenicity);
- solid papillary projections into the cyst;
- bilateral lesions;
- ascites;
- intra-abdominal metastases.

The level of cancer antigen 125 (CA-125; a glycoprotein expressed on tissue derived from coelomic and Müllerian epithelia) in serum is measured; the normal cut-off value is 35 U/mL. Elevated levels are found in 50 per cent of patients with stage I disease and >90 per cent of those with advanced disease. However, CA-125 levels are also elevated in other cancers, e.g., pancreas, breast, lung and colon. Levels may even be raised during menstruation; in benign conditions such as endometriosis, PID and liver disease; if ascites or other effusions are present; and after a recent laparotomy. The value of combining the ultrasound and CA-125 measurements is such that a post-menopausal woman with a simple, unilateral, unilocular cyst of <5 cm in diameter and a normal serum CA-125 level should be managed conservatively (Summary box 80.7).

Unfortunately, there are still no effective screening methods for ovarian cancer for the general population. Hence, the preliminary results of the UK Collaborative Trial of Ovarian Cancer Screening are of great interest. The study has recruited over 200,000 women, aged 50–74 years, who have been randomised to a control arm or one of two screening strategies: primary screening using measurement of serum CA-125 levels followed by transvaginal ultrasound as a second-line test or transvaginal ultrasound alone. The two screening procedures were similar in terms of sensitivity for all primary ovarian and Fallopian tube cancers, but specificity was higher with combined screening (99.8 versus 98.2 per cent; p < 0.001).

There is also no consensus regarding how women who are at high risk because of a family history should be screened, i.e., those with a first-degree relative affected by cancer within a family that meet one of the following criteria:

- Two or more individuals with ovarian cancer, who are first-degree relatives of each other.
- One individual with ovarian cancer at any age and one with breast cancer diagnosed at <50 years, who are first-degree relatives of each other (or second-degree relatives if the transmission is paternal).
- One relative with ovarian cancer at any age and two with breast cancer diagnosed at <60 years, who are connected by first-degree relationships (or second-degree relationships if the transmission is paternal).
- Known carrier of relevant cancer gene mutations (e.g., BRCA1 or BRCA2).
- Untested first-degree relative of a predisposing gene carrier.
- Three or more family members with colon cancer or two with colon cancer and one with stomach, ovarian, endometrial, urinary tract or small bowel cancer in two generations. One of these cancers must be diagnosed at <50 years of age (Lynch syndrome).
- An individual with both breast and ovarian cancer.

**Summary box 80.7**

**Basic tests on suspicion of ovarian malignancy**

- Ultrasonography: findings that suggest cancer include a solid component, surface excrescences, size >6 cm, irregular shape and low vascular resistance on transvaginal Doppler flow studies.
- A pelvic mass plus ascites usually indicates ovarian cancer but sometimes indicates Meigs’ syndrome (a benign fibroma with ascites and right hydrothorax).
- Computed tomography scan or magnetic resonance imaging is usually carried out before surgery to determine the extent of the cancer.
- Tumour markers, including the β-subunit of human chorionic gonadotropin (β-hCG), lactate dehydrogenase, α-fetoprotein, inhibin and CA-125, are also measured.
- CA-125 is elevated in 80 per cent of advanced epithelial ovarian cancers, but may be mildly elevated in endometriosis, pelvic inflammatory disease, pregnancy, fibroids, peritoneal inflammation and non-ovarian peritoneal cancer.
Some genetic mutations are known to predispose women to ovarian cancer, e.g. BRCA1 and BRCA2 and the mismatch repair genes associated with HNPCC (Lynch syndrome) families. BRCA1 mutations confer a 30 per cent lifetime risk of ovarian cancer up to the age of 60 years; the figure for BRCA2 mutations is 27 per cent up to the age of 70 years. The mismatch repair genes confer an increased lifetime risk of ovarian cancer of 9–12 per cent, in addition to the increased risk of endometrial cancer (see above under Vaginal bleeding in the non-pregnant state). Referral to a specialist cancer genetics service is advisable. Women at high risk of ovarian cancer may be offered prophylactic oophorectomy, especially as they may also be at increased risk of breast cancer and there is some evidence to suggest that oophorectomy reduces breast cancer risk in these women. Unfortunately, there is no proven role for screening in women at high risk.

Staging (Table 80.5) is performed at laparotomy via a midline incision if disease is suspected preoperatively by:

- Careful evaluation of all peritoneal surfaces.
- Four washings of the peritoneal cavity: diaphragm, right and left abdomen, pelvis.
- Infracolic omentectomy.
- Selected lymphadenectomy of the pelvic and para-aortic lymph nodes.
- Biopsy and/or resection of any suspicious lesions, masses and any adhesions.
- Random blind biopsies of normal peritoneal surfaces, including that from the undersurface of the right hemidiaphragm, bladder reflection, cul-de-sac, right and left paracolic recesses and both pelvic side walls.
- Total abdominal hysterectomy and bilateral salpingo-oophorectomy.
- Appendicectomy for mucinous tumours; if a routine appendicectomy results in an intraoperative suspicion of a mucinous tumour, the surgeon should take washings and a biopsy from any suspicious area.

Surgery is the mainstay of treatment for ovarian cancer. The staging laparotomy and histological findings provide accurate information about prognosis and postoperative therapy. The general principle is cytoreductive surgery followed by combination chemotherapy; only a minority of patients with ovarian cancer need bowel resected during the primary procedure or surgery for recurrent disease. The only exception to this rule is a young woman with stage I disease or a borderline tumour who requests unilateral oophorectomy to conserve her fertility.

Stage I/grade 1 epithelial adenocarcinoma requires no postoperative therapy. Stage I/grade 2 or 3 cancers and stage II cancers require six courses of chemotherapy (typically, paclitaxel and carboplatin). Stage III or IV cancer requires six courses of similar chemotherapy. Intraperitoneal chemotherapy or high-dose chemotherapy with bone marrow transplantation is under study. Radiation therapy is used infrequently. Even if chemotherapy results in a complete clinical response (i.e. normal physical examination, normal serum CA-125 and negative CT scan of the abdomen and pelvis), about 50 per cent of such patients with stage III or IV cancer will have residual tumour. Of patients with persistent elevation of CA-125, 90–95 per cent have residual tumour.

Ovarian stimulation with oocyte or embryo freezing has been reported in patients with low-grade tumours who wish to preserve fertility, but the effect of this on the underlying disease is as yet unknown and it must therefore be carried out with caution.

Transplantation

81 Transplantation 1407
HISTORICAL PERSPECTIVE

Since early times, the idea of tissue and organ transplantation has captured the imagination of successive generations and, over the centuries, numerous fanciful descriptions of successful transplants have been recorded. One of the most widely cited early examples is that of the Christian Arab Saints Cosmas and Damian. Around ad 300, they were reputed to have successfully replaced the diseased leg of a patient with that from another man who had died several days earlier (Figure 81.1).

The modern era of transplantation began in the 1950s (Table 81.1) and relied on surgical techniques for anastomosing blood vessels that had been developed at the beginning of the twentieth century by Mathieu Jaboulay and Alexis Carrel. The first successful kidney transplant was a living-donor transplant performed between identical twins in 1954 at the Brigham Hospital in Boston by Joseph Murray and colleagues. This, and other kidney transplants between identical twins, demonstrated the technical feasibility of kidney transplantation, but attempts to perform renal transplantation when the donor and recipient were not genetically identical failed because no effective immunosuppressive therapy was available (Figure 81.2). Then, in 1959, Schwartz and Dameshek discovered that 6-mercaptopurine had immunosuppressive properties, and Calne showed that azathioprine, a derivative of 6-mercaptopurine, prevented rejection of canine kidney transplants. From the early 1960s, a combination of azathioprine and corticosteroids was used with moderate success in the clinic to prevent graft rejection after

Definitions

- Allograft: an organ or tissue transplanted from one individual to another
- Alloantigen: transplant antigen
- Alloantibody: transplant antibodies
- HLA: human leukocyte antigen, the main trigger to graft rejection
- Xenograft: a graft performed between different species
- Orthotopic graft: a graft placed in its normal anatomical site
- Heterotopic graft: a graft placed in a site different from that where the organ is normally located

Summary box 81.1

Graft Rejection

Allografts provoke a powerful immune response that results in rapid graft rejection unless immunosuppressive therapy is given. The pioneering studies of Medawar in the 1940s and 1950s firmly established that allograft rejection was due to an immune response and not a non-specific inflammatory response, and subsequent studies demonstrated that T lymphocytes play an essential role in mediating rejection.

Allografts trigger a graft rejection response because of allelic differences at polymorphic genes that give rise to histocompatibility antigens (transplant antigens) of which ABO blood group antigens and human leukocyte antigens (HLA) are the most important.

ABO Blood Group Antigens

The ABO blood group antigens are expressed not only by red blood cells, but by most other cell types as well. It is vitally

Sir Ray York Calne, Emeritus Professor of Surgery, The University of Cambridge, Cambridge, UK. In 1968 he performed Europe’s first liver transplant. He was associated with the world’s first liver, heart and lung transplant in 1987. He was elected Fellow of the Royal Society in 1974. He is an accomplished painter who has painted many of his transplant patients and has had exhibitions worldwide.

Sir Peter Brian Medawar, 1915–1987, a zoologist and immunologist and who was Director of the National Institute of Medical Research, London, UK. He shared the 1960 Nobel Prize for Physiology or Medicine with Sir Frank Macfarlane Burnet, for his research into immunological tolerance.

Jean-Francois Borel, a research scientist working in Switzerland.

Figure 81.2 One of the early Boston recipients of a kidney transplant from an identical twin, shown here with her twin sister and their children.
important, for all types of organ allograft, to ensure that recipient do not unintentionally receive a graft that is ABO blood group compatible otherwise naturally occurring anti-A or anti-B antibodies will likely cause hyperacute graft rejection.

Permissible transplants are:
- group O donor to group O, A, B or AB recipient;
- group A donor to group A or AB recipient;
- group B donor to group B or AB recipient;
- group AB donor to group AB recipient.

There is no need to take account of rhesus antigen compatibility in organ transplantation.

**HLA antigens**

Allograft rejection (in blood group-compatible grafts) is directed predominantly against HLA – a group of highly polymorphic cell-surface molecules. HLA are strong transplant antigens by virtue of their special physiological role as antigen recognition units for display of antigens from foreign pathogens for recognition by T lymphocytes. It was through their role in stimulating graft rejection responses that their existence was first demonstrated by Dausset in 1958, hence their description as major histocompatibility antigens (Summary box 81.2).

### Summary box 81.2

**HLA antigens**
- Are the most common cause of graft rejection
- Their physiological function is to act as antigen recognition units
- Are highly polymorphic (amino acid sequence differs widely between individuals)
- HLA-A, -B (class I) and -DR (class II) are most important in organ transplantation

There are two types of HLA molecule: HLA class I and HLA class II (Table 81.2). They are broadly similar in structure (Figure 81.3) but have different cell expression profiles. HLA class I antigens are present on all nucleated cells, whereas HLA class II antigens have a more restricted distribution and are expressed most strongly on antigen-presenting cells, such as dendritic cells, macrophages and B lymphocytes. T cells recognize HLA molecules via their T-cell receptor but full T-cell activation also requires the delivery of an additional or second signal delivered by the interaction of costimulatory molecules on the surface of the antigen-presenting cell and T cell (Figure 81.4).

### Effector mechanisms of rejection

HLA antigens expressed by graft cells activate T cells and stimulate them to proliferate in response to interleukin-2 (IL-2) and other T-cell growth factors. Activated CD4 T cells, through release of cytokines, play a central role in orchestrating the various effector mechanisms responsible for graft rejection (Figure 81.5). The cellular effectors of graft rejection include cytotoxic CD8 T cells, that recognise donor HLA class I antigens expressed by the graft and cause target cell death by releasing lytic molecules such as perforin and granzyme. Graft-infiltrating CD4 T cells, which recognise donor HLA class II antigens, mediate direct target cell damage and are also able, by releasing proinflammatory cytokines such as interferon-γ, to recruit and activate macrophages that act as non-specific effector cells. Finally, CD4 T cells provide essential T-cell help for B lymphocytes that differentiate into plasma cells and produce antibodies.

**Table 81.2 HLA class I and HLA class II molecules.**

![Figure 81.3 The three-dimensional structure of the extracellular domains of human leukocyte antigen (HLA) class I and class II. The α1 and α2 domains of class I and the α1 and β1 domains of class II form a cleft that is floored by a β-pleated sheet and walled by two α-helices. The cleft binds an antigenic peptide and displays it on the cell surface for recognition by a T lymphocyte. (Redrawn with permission from Stern and Wiley [1994] Structure: 245–52.)](image-url)
alloantibodies that bind to graft antigen and induce target cell injury directly or through antibody-dependent, cell-mediated cytotoxicity.

**Types of allograft rejection**

Allograft rejection can be divided into three distinct types (Summary box 81.3):

1. **Hyperacute rejection** (occurs immediately);
2. **Acute rejection** (usually occurs in the first six months);
3. **Chronic rejection** (occurs months and years after transplantation).

Allograft rejection manifests itself as functional failure of the transplant and is confirmed by histological examination. Biopsy material is obtained from renal and pancreas grafts by needle biopsy, and from hepatic grafts by percutaneous or transjugular liver biopsy. Cardiac grafts are biopsied by transjugular endomyocardial biopsy and lung grafts by transbronchial biopsy. After small intestinal transplantation, mucosal biopsies are obtained from the graft stoma or more proximally by endoscopy.

A standardised histological grading system, termed the Banff classification (named after the Canadian town where the initial scientific workshop was held), defines the presence and severity of allograft rejection after organ transplantation.

**Hyperacute rejection**

This is due to the presence in the recipient of preformed antibodies against HLA class I antigens expressed by the donor. These arise from a previous blood transfusion, a failed transplant and pregnancy. This type of rejection also occurs if an ABO blood group-incompatible organ graft is performed inadvertently. After revascularisation of the graft, antibodies bind immediately to the vasculature, activate the complement system and cause extensive intravascular thrombosis, interstitial haemorrhage and graft destruction within minutes and hours. Kidney transplants are particularly vulnerable to hyperacute graft rejection, whereas heart and liver transplants are relatively resistant. It is not clear why the liver is resistant to hyperacute rejection. One factor may be that it is less susceptible to ischaemia than the kidney by virtue of its dual blood supply: 60 per cent of

**Summary box 81.3**

**Types of graft rejection**

- **Hyperacute rejection**
  - Immediate graft destruction due to ABO or preformed anti-HLA antibodies
  - Characterised by intravascular thrombosis and interstitial haemorrhage
- **Acute rejection**
  - Usually occurs during first six months
  - T cell dependent
  - May be cell-mediated, antibody-mediated or both
  - Usually reversible
- **Chronic rejection**
  - Occurs after first six months
  - Most common cause of graft failure
  - Antibodies play an important role
  - Non-immune factors contribute to pathogenesis
  - Characterised by myointimal proliferation in graft arteries leading to ischaemia and fibrosis

---

**Figure 81.4** Molecular events involved in T-cell activation by an antigen-presenting cell. T-cell activation requires the delivery of two distinct signals to the T cell. The first signal is delivered by ligation of the TCR/CD3 complex with human leukocyte antigen (HLA)/peptide complex. The second signal is delivered following the interaction between pairs of costimulatory molecules such as CD28 with CD80/86 and CD154 with CD40.

**Figure 81.5** The central role of the CD4 T cell in orchestrating the various effector mechanisms responsible for allograft rejection. APC, antigen-presenting cell; DTH, delayed-type hypersensitivity; IFN-γ, interferon-gamma; IL, interleukin; MΦ, macrophage; MHC, major histocompatibility complex; NK, natural killer; Tc, T cytotoxic cell; Tcp, T cytotoxic precursor cell; TCR, T-cell receptor.
the hepatic blood supply is derived from the portal vein and 40 per cent from the hepatic artery.

Hyperacute rejection can be avoided by ensuring ABO blood group compatibility and by performing a cross-match test on recipient serum to ensure that there are no clinically relevant antibodies directed against HLA antigens expressed by a prospective kidney donor.

**Acute rejection**

This usually occurs during the first six months of transplantation but may occur later. It is mediated predominantly by T lymphocytes, but alloantibodies may also play an important role. Acute rejection is characterised by mononuclear cell infiltration of the graft (Figure 81.6). The mononuclear cell infiltrate is heterogeneous and includes cytotoxic T cells, B cells, NK cells and activated macrophages. Antibody-mediated damage may also be present as evidenced by the deposition of the complement component C4d within the graft microvasculature (Figure 81.7). All types of organ allograft are susceptible to acute rejection, and although relatively common (typically occurring in around 20–30 per cent of grafts), most episodes of acute rejection can be reversed by additional immunosuppressive therapy.

**Chronic rejection**

This usually occurs after the first six months. All types of transplant are susceptible to chronic rejection, and it is the major cause of allograft failure. Interestingly, the liver is more resistant than other organs to the destructive effects of chronic rejection. The pathophysiology of chronic rejection is not well understood. The underlying mechanisms are immunological, and alloantibodies are thought to be a major cause although cellular effector mechanisms may also contribute. Alloantigen-independent factors also contribute. The risk factors for chronic rejection of a kidney transplant are:

- previous episodes of acute rejection;
- poor HLA match;
- long cold ischaemia time;
- cytomegalovirus (CMV) infection;
- raised blood lipids;
- inadequate immunosuppression (including poor compliance).

The single most important risk factor for chronic rejection after kidney transplantation is acute rejection (with vascular inflammation) and recurrent episodes of acute rejection. Because non-immune factors often contribute significantly to the long-term failure of a kidney transplant, the term ‘chronic allograft nephropathy’ is sometimes used.

The histological picture of chronic rejection after organ transplantation is dominated by vascular changes, with the development of myointimal proliferation in arteries, which results in ischaemia and fibrosis (Figure 81.8). In addition to vasculopathy, there are organ-specific features of chronic graft rejection. These are:

- kidney: glomerular sclerosis and tubular atrophy;
- pancreas: acinar loss and islet destruction;
- heart: accelerated coronary artery disease (cardiac allograft vasculopathy);
- liver: vanishing bile duct syndrome;
- lungs: obliterative bronchiolitis.

The histological picture of chronic rejection after organ transplantation is dominated by vascular changes, with the development of myointimal proliferation in arteries, which results in ischaemia and fibrosis (Figure 81.8). In addition to vasculopathy, there are organ-specific features of chronic graft rejection. These are:

- kidney: glomerular sclerosis and tubular atrophy;
- pancreas: acinar loss and islet destruction;
- heart: accelerated coronary artery disease (cardiac allograft vasculopathy);
- liver: vanishing bile duct syndrome;
- lungs: obliterative bronchiolitis.
Chronic rejection causes functional deterioration in the graft, resulting after months or years in complete graft failure. Unfortunately, currently available immunosuppressive therapy has had little effect in preventing chronic rejection.

**Graft-versus-host disease**

Although the main immunological problem after transplantation is graft rejection, the reciprocal problem of graft-versus-host reaction is occasionally seen following certain types of organ transplantation. Some donor organs (particularly liver and small bowel) contain large numbers of lymphocytes, and these may react against HLA antigens expressed by recipient tissues, leading to graft-versus-host disease (GVHD). GVHD frequently involves the skin, causing a characteristic rash on the palms and soles. It may also involve the liver (after small bowel transplantation) and the gastrointestinal tract (after liver transplantation). GVHD is a serious and sometimes fatal complication.

**HLA matching**

HLA molecules are encoded by the major histocompatibility complex (MHC), a cluster of genes situated on the short arm of chromosome 6 (Figure 81.9). The HLA class I antigens comprise HLA-A, -B and -C, and the HLA class II antigens comprise HLA-DR, -DP and -DQ. Expression of MHC genes is co-dominant, i.e., the genes on both the maternally derived and the paternally derived chromosomes are expressed. Consequently, an individual may express between 6 and 12 different HLA antigens, depending on the degree of homozygosity (shared genes) at individual loci.

The HLA haplotype inherited from each parent is usually inherited as a complete haplotype, according to simple Mendelian genetics (Figure 81.10). In deceased donor renal transplantation (but not other types of organ transplantation), attempts are usually made to match the donor and recipient for as many of the relevant HLA antigens as possible. In addition to reducing the risk of graft loss from rejection, a well-matched kidney allograft that subsequently fails is less likely to cause sensitisation to the HLA antigens that it expresses. It is particularly important in children and young adults to avoid, where possible, grafts that are mismatched for common HLA antigens because, if retransplantation is required subsequently, it may be difficult to find an organ donor who does not express the antigens to which the recipient has become sensitised. In terms of organ transplantation, HLA-A, -B and -DR are the most important antigens to take into account when matching donor and recipient in an attempt to reduce the risk of graft rejection (Figure 81.11).

HLA matching has a relatively small but definite beneficial effect on renal allograft survival (HLA-DR > HLA-B > HLA-A). Recipients who receive well-matched renal allografts may require less intensive immunosuppression and also are troubled less by rejection episodes. It is common practice to express the degree of HLA matching between the donor and recipient in terms of whether or not there are mismatches at each locus for HLA-A, -B and -DR. A ‘000 mismatch’ is a ‘full-house’ or complete match, whereas a ‘012 mismatch’ is matched at...
HLA-A loci, has one mismatched HLA-B antigen and is mismatched for both DR antigens. Deceased donor kidneys are allocated in some countries, including the UK, by a points system that optimises HLA matching but also takes into account other factors, such as time on the waiting list, sensitisation to HLA antigens and the age relationship between the donor and recipient. Allocation of organs for transplantation must also take into account the relative size of donor and recipient. This is not an issue in renal transplantation, and adult kidneys can be readily used for paediatric recipients (and vice versa). However, in the case of heart, lung, liver and small bowel transplantation, it is important to consider size compatibility between the donor and recipient. In the case of liver transplants, HLA matching does not confer an advantage and, although it is beneficial in cardiac transplantation, it is not practicable because of the relatively small size of the recipient pool and the short permissible cold ischaemic time.

**THE TISSUE-TYPING LABORATORY**

Successful organ transplantation requires a close-working relationship between the tissue-typing laboratory and the clinical transplant team. The tissue-typing laboratory carries out three key tasks. First, they determine the HLA type (‘tissue type’) of all potential organ transplant recipients and organ donors. This is achieved by applying polymerase chain reaction-based DNA-typing techniques to samples of peripheral blood. Second, they perform a cross-match test to exclude the presence in a recipient of clinically significant circulating antibodies to HLA antigens expressed by a potential organ donor that would result in rapid or hyperacute graft rejection. This involves incubating recipient sera with donor lymphocytes prepared from either blood or lymphoid tissue. The presence of antidonor antibodies is detected in a conventional cytotoxic cross-match assay by adding rabbit complement along with indicator dyes and visualising target cell death. More often now a flow cytometric cross-match is performed as well as, or instead of, a cytotoxic cross-match. Third, the tissue-typing laboratory determines the HLA specificity of circulating anti-HLA antibodies in recipients before and after organ transplantation to guide organ allocation and immunosuppressive therapy. This task has been revolutionised by the availability of solid phase assays, particularly Luminex technology, where patient sera are incubated with a panel of latex beads coated with purified HLA molecules and antibody binding detected by flow cytometric analysis.

Patients on the renal transplant waiting list should be screened for the development of HLA antibodies on a regular basis and especially after potential priming to HLA antigens by blood transfusion.

If, when considering renal transplantation the cross-match test is strongly positive, transplantation should not proceed, otherwise hyperacute rejection is likely. Antibodies directed against HLA class II antigens, unlike those to HLA class I, do not usually cause hyperacute rejection but are associated with acute rejection and a poor clinical outcome. Patients awaiting heart transplantation are also screened for the presence of HLA antibodies and those with preformed antibodies are subjected to a prospective cross-match test. Although heart allografts rarely undergo hyperacute rejection, transplantation in the presence of a positive cross-match is associated with graft loss from accelerated acute rejection. Even in the presence of a strongly positive cross-match test, liver transplants rarely undergo hyperacute rejection, although long-term survival is reduced.

**IMMUNOSUPPRESSIVE THERAPY**

A range of different agents are available that act at different sites during T-cell activation to prevent rejection (Table 81.3 and Figure 81.12). They can be classified according to their principal mode of action.

Calcineurin inhibitors (ciclosporin and tacrolimus)

Ciclosporin and tacrolimus are the mainstay of most modern immunosuppressive protocols for organ transplantation. Although structurally distinct, they exert their principal immunosuppressive effect through the same intracellular pathway. Each of the two agents binds within the T cell to a cytoplasmic protein or immunophilin (ciclosporin binds to cyclophilin and tacrolimus to FK-binding protein). The resulting immunophilin–drug complex then blocks the activity of calcineurin (a phosphatase) within the cytoplasm of the T cell. Calcineurin plays a critical role in facilitating the transcription of IL-2, the main T-cell growth factor, and other cytokines after T-cell activation. By blocking cytokine synthesis, ciclosporin and tacrolimus exert a potent immunosuppressive effect. The two agents share a number of side effects, the most notable of which is nephrotoxicity (Table 81.4). Ciclosporin sometimes causes cosmetic side effects (hirsutism and gingival hypertrophy) that may be distressing, particularly in younger female recipients. The calcineurin inhibitors (CNIs) have a relatively small therapeutic window. Their immunosuppressive action, as well as their side effects, is dependent on their blood concentration, and monitoring of whole-blood drug levels is an important guide to optimal therapy. Ciclosporin and tacrolimus are broadly equivalent in terms of long-term graft survival but increasing evidence suggests tacrolimus is more effective in reducing acute rejection. The choice between the two agents depends on the preference of the transplant unit and on individual patient tolerance to the different side effects of the two agents.

All immunosuppressive agents increase the risk of infection.

Antiproliferative agents (azathioprine and mycophenolate)

Lymphocytes are among the most rapidly proliferating cells in the body, and lymphocyte proliferation and clonal expansion is an integral part of the immune response to an allograft. The antiproliferative agents available for immunosuppression include azathioprine and mycophenolic acid preparations (mycophenolate mofetil (MMF) and mycophenolic acid sodium (MPAS)). Azathioprine is converted in the liver to its active metabolite, 6-mercaptopurine, which blocks purine metabolism and thereby inhibits cellular proliferation. Mycophenolic acid (MPA) preparations are more expensive than azathioprine but have largely replaced it as the agents of choice. After ingestion, MMF is converted to its active metabolite MPA. It inhibits the enzyme inosine monophosphate dehydrogenase, which is the rate-limiting enzyme in the de novo pathway of purine nucleotide synthesis. Because lymphocytes do not have a salvage pathway for purine synthesis, their ability to proliferate is selectively impaired. The main side effects of azathioprine and MPA are bone marrow suppression and gastrointestinal symptoms.

Steroids

Steroids are an important component of many immunosuppressive regimens. Glucocorticoids are potent anti-inflammatory agents and have wide-ranging effects on the immune response. Because of their numerous and well-known side effects, some centres attempt to gradually withdraw steroids from patients who have stable graft function after transplantation, but this sometimes precipitates a rejection episode and necessitates recommencement of steroids.

Antibody therapies

Monoclonal antibodies directed against the IL-2 receptor on T lymphocytes (CD25) are commonly given at the time of transplantation to temporarily augment the effects of calcineurin blockade during the early post-transplant period. Their effect lasts for a few weeks only and they lack any significant agent-specific side effects. Polyclonal antibody (antithymocyte globulin (ATG)) and monoclonal antibody preparations (alemtuzumab (anti-CD52 expressed on T cells and dendritic cells) and basiliximab (anti-CD25 directed against T cells)) are also quite widely used as more potent and alternative induction agents. They cause a temporary depletion of circulating lymphocytes that reduces rejection but may lead to an increase in infection and malignancy. In addition to their use as induction agents, antibody preparations may be used to treat acute rejection episodes that fail to respond to steroid therapy.

The monoclonal anti-CD20 antibody (rituximab) depletes B lymphocytes and is widely used as a component of desensitisation protocols to enable ABO and HLA antibody-incompatible renal transplantation. It may also be helpful for the treatment of antibody-mediated acute rejection although its efficacy here is limited because it does not deplete antibody-producing plasma cells.

Mammalian target of rapamycin inhibitors (sirolimus and everolimus)

Sirolimus and its structural analogue everolimus are, like tacrolimus, macrolides that bind within T lymphocytes to FK-binding protein. However, their mode of action is completely different to that of both ciclosporin and tacrolimus.
They act by inhibiting an intracellular kinase called mammalian target of rapamycin (mTOR) and interfere with intracellular signalling from the IL-2 receptor, arresting T-cell division in the G1 phase. In contrast to CNIs they are not nephrotoxic. However, their side effect profile includes lymphocele formation, impaired wound healing, an adverse effect on the blood lipid profile, thrombocytopenia and very occasionally pneumonitis. mTOR inhibitors may have antitumour activity and the potential value of this effect in transplant patients is under investigation. Although the negative effect on wound healing and lymphocele formation limits the immediate use of mTOR inhibitors after transplantation, switching from CNIs to mTOR inhibitors is being used increasingly as a strategy to minimise CNI-induced nephrotoxicity.

T-cell costimulatory blockers
CTLA-4Ig (belatacept, LEA29Y) is a fusion protein comprising the extracellular domain of CTLA-4 fused to human IgFc. It binds to the costimulatory ligands CD80 and CD86 expressed on antigen-presenting cells and as a result prevents them from delivering the costimulatory signals to the T cells that are required for full T-cell activation. It has recently been shown in renal transplantation to provide an effective alternative to CNIs when given by regular i.v. injection, thereby avoiding the metabolic, cardiovascular and nephrotoxic effects of CNIs. Although its future looks very promising, a potential concern is that it may be associated with an increased risk of post-transplant lymphoproliferative disease (PTLD).

Immunosuppressive regimens
When selecting an immunosuppressive regimen, the challenge is to provide levels of immunosuppression that are sufficient to protect the graft from rejection without exposing the recipient to excessive risk from infection and malignancy as a result of non-specific immunosuppression (Summary box 81.4). Immunosuppressive therapy is started at the time of transplantation and is continued indefinitely (as maintenance therapy), although the requirement for immunosuppression is highest in the first few weeks after transplantation when the risk of acute rejection is greatest. Immunosuppressive protocols vary, but all use a combination of immunosuppressive agents acting at different points in the pathway of lymphocyte activation. Most currently include a CNI (ciclosporin or tacrolimus) as the main agent and often this is supplemented with anti-CD25 monoclonal antibody induction therapy. CNIs are usually combined with an antiproliferative agent (most often MMF) and steroids, so-called triple therapy. Less often, a CNI is used with an antiproliferative agent alone or with steroids alone (dual therapy). When there is particular concern about acute rejection, polyclonal or monoclonal antibody preparations are administered followed by a CNI, an antiproliferative agent and steroids.

The principles of immunoprophylaxis are similar for all types of organ transplantation. Interestingly, liver grafts seem to be less susceptible to rejection for reasons that are still unclear. The mTOR inhibitors have been shown to be effective immunosuppressive agents for preventing acute rejection following kidney transplantation and they provide a non-nephrotoxic alternative to CNIs for maintenance therapy. They have a similar safety profile to CNIs in terms of post-transplant infection but some of their agent-specific side effects are of potential concern and their clinical niche is still to be fully determined. Similarly, the potential role that CTLA-4Ig will find as an alternative to CNIs remains to be seen.

Acute rejection occurs in up to around 30 per cent of transplant recipients but usually responds to a short course of high-dose steroid therapy. If the response to steroids is inadequate or if acute rejection recurs, acute rejection can often be treated successfully by recourse to antilymphocyte globulin (ALG) therapy.

**COMPLICATIONS OF IMMUNOSUPPRESSION**

As well as the agent-specific side effects already mentioned, the immunosuppressive agents used in organ transplantation cause non-specific immunosuppression and increase the risk of both infection and malignancy (Summary box 81.5).

> **Summary box 81.5**
>
> **Side effects of non-specific immunosuppression**
>
> **Infection**
> Transplant recipients are at high risk of opportunistic infection, especially by viruses
> Bacterial and fungal infections are also common
> Risk of infection is greatest during first six months
> Chemoprophylaxis is important for high-risk patients
> Viral infection may result from reactivation of latent virus or from primary infection
> Cytomegalovirus is a major problem
> Pretransplant vaccination against community-acquired infection should be considered
>
> **Malignancy**
> Most types of cancer are more common after transplantation
> Recipients, especially children, are at risk of post-transplant lymphoproliferative disease (PTLD)
> There is a very high risk of squamous cancer of the skin and recipients should have regular skin review

**Infection**
Transplant recipients receiving immunosuppressive therapy are at high risk from opportunistic infection, especially by viruses. Opportunistic infection is a potential problem in all transplant recipients, but those receiving aggressive immunosuppressive...
therapy are most at risk. Chemoprophylaxis is important in high-risk recipients, and early recognition followed by prompt and aggressive treatment of infection is essential in all transplant recipients. Pretransplant vaccination against community-acquired infections should be considered.

**Bacterial infection**

The risk of bacterial infection is highest during the first month after transplantation. Transplant recipients are, like any patient undergoing major surgery, at risk of bacterial infections in the wound, respiratory tract and urinary tract. It is standard practice to give a broad-spectrum antibiotic to cover the perioperative period as prophylaxis against wound infection and possible bacterial contamination of the donor organ. The risk of bacterial infection is greatest in transplant recipients who are critically ill before or after surgery and are in the intensive care unit with indwelling catheters and lines. After recovery from surgery, the risk of bacterial infection is much reduced. Tuberculosis is a concern in patients who have previously had mycobacterial infection and in patients from the Indian subcontinent, and it is usual to give them chemoprophylaxis for a period of 6–12 months after transplantation.

**Viral infection**

The risk of viral infection is highest during the first six months after transplantation and the most common problem is CMV infection. CMV disease may arise because of reactivation of latent infection or because of primary infection that can be transmitted by an organ from a CMV-positive donor. Recipients at most risk from CMV infection are those who are CMV seronegative (i.e. those who have not been infected previously with CMV) and receive an organ from a CMV-seropositive donor (about half of all UK donors are CMV seropositive). Unfortunately, matching seronegative donors with seronegative recipients is not practicable. Without prophylaxis, CMV disease typically presents at 4–8 weeks with a high swinging fever, leucopenia and leukopenia. The severity of the disease is variable and the clinical picture depends on the organ system most affected. It may present as:

- pneumonia
- gastrointestinal disease
- hepatitis
- retinitis
- encephalitis.

Severe CMV disease is potentially fatal. Prophylaxis for CMV consists of administration of antiviral agents, most commonly valganciclovir; aciclovir and valaciclovir are cheaper but less effective alternatives. A diagnosis of active CMV infection is confirmed by polymerase chain reaction (PCR) to detect viral DNA in whole blood, and by histological examination of biopsy material. Treatment is with antiviral agents (either oral valganciclovir or i.v. ganciclovir) and is more effective when given pre-emptively on the basis of increased viral load detected by quantitative PCR analysis of peripheral blood. Herpes simplex virus (HSV) infection is common after transplantation and is usually due to reactivation of latent infection. It causes mucocutaneous lesions around the mouth and sometimes the genitalia. These usually respond to topical treatment with aciclovir, but in severe cases systemic antiviral therapy is needed. Disseminated HSV infection is rare.

BK virus is emerging as an important cause of graft dysfunction after renal transplantation. Infection with BK virus is almost universal during childhood, with latent infection in the epithelium of the urinary tract. Immunosuppression causes lytic BK virus replication with graft involvement in 1–5 per cent of renal transplants. The only effective treatment is to reduce the level of immunosuppression to allow natural immune mechanisms to regain control of the virus.

Herpes zoster infection, as a result of reactivation of latent varicella zoster virus, occurs more frequently in transplant patients and should be treated with systemic antiviral therapy. Primary varicella zoster virus infection (chickenpox) is potentially very serious in immunosuppressed patients but is relatively uncommon as most adults have acquired immunity.

**Fungal infection**

Pneumocystis jiroveci (previously designated Pneumocystis carinii and wrongly classified as a protozoa) is one of the more important fungal infections after transplantation. It occurs during the first few months and presents with respiratory symptoms. The diagnosis is made by examination of bronchoalveolar lavage fluid or lung biopsy material for evidence of fungal infection (Figure 81.13). Chemoprophylaxis is highly effective and usually continued for up to six months after transplantation.

Other types of invasive fungal infections are uncommon in renal transplant recipients but infection with Candida or Aspergillus is more common after other types of organ transplantation. Fungal infection usually occurs in the first three months after transplantation, and early diagnosis and aggressive treatment are essential to avoid fatal infection.

**Malignancy**

After transplantation, there is an increased risk of developing most types of malignant disease but the risk is particularly high for those types of tumour in which viral infection plays an aetiological role. The increased risk of malignancy is particularly high for skin cancer and post-transplant lymphoproliferative disorder. Most of the skin cancers seen are squamous cell carc...
cinomas, but basal cell carcinoma and malignant melanoma are also more common than in the general population. The risk of skin cancer after transplantation rises with age and with exposure to sunlight, and it has been predicted that 50 per cent of transplant patients will develop a skin malignancy within 20 years of transplantation. Patients must be warned of this risk before they undergo transplantation and advised to take precautions to protect their skin from excessive sunlight. They should undergo regular review of their skin to detect early malignancy, and when malignant lesions occur they must be treated promptly and aggressively.

Post-transplant lymphoproliferative disorder is an abnormal proliferation of B lymphocytes, usually in response to Epstein–Barr virus infection. The condition presents in a variety of ways including as an infectious mononucleosis-type illness, as lymphadenopathy or with involvement of extranodal sites such as the tonsils, gastrointestinal tract, lung, liver or the transplanted organ (Figure 81.14). PTLD occurs in around 1–3 per cent of kidney and liver transplant recipients and the incidence is considerably higher in children. Those patients at most risk are those who have received aggressive immunosuppression. PTLD is a serious condition with an overall mortality of up to 50 per cent. If it is identified at an early stage, reduction or cessation of immunosuppressive therapy may cause disease regression and result in a cure. Chemotherapy is often given and antiviral therapy, surgery and radiotherapy may also have a role in treating established disease. Disseminated PTLD and central nervous system (CNS) involvement have a very poor prognosis.

Transplant patients also have a 300-fold increased risk of developing Kaposi’s sarcoma, although this malignancy is still very uncommon after transplantation.

ORGAN DONATION

The number of organs required to satisfy the needs of transplantation far exceeds the number of donor organs available. In the case of renal transplantation in the UK there are approximately 7000 patients waiting for transplantation, but only around 3500 transplants performed annually, which has led to a median waiting time for transplantation of three years. Similar shortages exist for liver and pancreas transplantation. For cardiovascular organs the shortage is even worse and not all patients who might benefit from transplantation are listed.

Organ donors may be obtained from living donors or from deceased donors (DD) and DD may be either brainstem-dead heart-beating donors (donation after brain death or DBD donors) or donation after circulatory death (DCD) donors. Living donation is limited to donation of the kidney and, to a much lesser extent, liver or lung lobe. DBD donors provide a majority of organs for transplantation for all organ types although DCD donors provide an increasing number of kidneys, livers, pancreas glands and lungs for transplantation (see Summary box 81.6). The approach to referral and consent for organ donation varies between countries. Some have ‘required request’ or ‘required referral’ systems in place where all patients dying in intensive care settings have to be referred for their potential suitability to be organ donors assessed. Some countries (e.g. Austria and Spain) have an ‘opt out’ or ‘presumed consent’ system, where the assumption is made that an individual wished to donate their organs for transplantation unless they specifically registered their objection before death. There is debate about whether such a policy alone increases organ donation and a concern expressed by some that individuals who may not have wanted to become organ donors may fail to opt out before death, and that conflict may occur with relatives and next of kin who may oppose organ donation.

Summary box 81.6

Overcoming the shortage of organs for transplantation

- Maximising donation after brain-death (DBD) donation
- Use of marginal DBD deceased donors
- Use of donation after circulatory death (DCD) donors
- Increased use of split liver transplantation
- Increased living donor kidney (and liver) transplantation

Donation after brain death donors

The majority of DD organs are obtained from patients in whom brainstem death has been diagnosed. Such donors were previously called ‘heart-beating deceased donors’ and in most brain death results from stroke or traumatic head injury. Brain
death occurs when severe brain injury causes irreversible loss of the capacity for consciousness combined with the irreversible loss of the capacity for breathing. In most countries, it is accepted that the condition of brain death equates in medical, legal and religious terms with death of the patient. The concept of brain death arose through necessity in the management of patients with irreversible brain damage on life support when there was no prospect for recovery. It was not in the interest of such patients, their relatives or the hospital in which they were being treated to delay their inevitable demise by continuing with futile life support. Acceptance of the concept of brain death had major implications for organ transplantation as it allowed the possibility for removal of viable organs from brain-dead patients before their circulation failed.

In the UK and many other countries, brain death is defined in terms of permanent functional death of the brainstem as neither consciousness nor spontaneous respiration is possible in the absence of a functional brainstem. A diagnosis of brainstem death should be considered only when certain preconditions have been met. The patient must have suffered major brain damage of known aetiology, be deeply unconscious and require ventilatory support. Particular care must be taken to ensure that muscle relaxant agents and drugs with known CNS depressant effects are not contributing to the clinical picture. Hypothermia, profound hypotension and metabolic or hormonal conditions that may contribute to CNS depression and confound the diagnosis of brainstem death must also be excluded. When the necessary preconditions have been satisfied, formal clinical assessment of the brainstem reflexes can be undertaken (Table 81.5). The UK guidelines state that the tests should be performed on two separate occasions by two clinicians experienced in this area. At least one of the two clinicians should be a consultant and neither should be connected with the transplant team. The time that must elapse between the two sets of brainstem tests is not specified in the guidelines and is determined on the basis of clinical judgement. In the UK, there is no requirement to perform electrophysiological or brain perfusion studies to aid the diagnosis of brainstem death. Particular care is required in the diagnosis of brainstem death in neonates and infants.

**Donation after circulatory death donors**

The number of potential DBD donors has remained relatively static or even declined as a result of changes in neurosurgical practice and improved road safety. To address the rising demand for organ transplantation there has been a major trend towards increasing use of organs from DCD donors.

DCD donors can be grouped according to the Maastricht classification as follows:

- category 1: dead on arrival at hospital;
- category 2: resuscitation attempted without success;
- category 3: ‘awaiting cardiac arrest’ after withdrawal of support;
- category 4: cardiac arrest while brain dead;
- category 5: cardiac arrest and unsuccessful resuscitation in hospital.

Maastricht categories 1, 2 and 5 donors are sometimes referred to as uncontrolled DCD donors. The warm ischaemic time of organs from these three categories of donor is usually longer and less predictable than in the case of categories 3 and 4 (controlled) donors. The majority of DCD donor organs used for transplantation in the UK, US and several other European countries are from controlled (category 3) donors who have died in intensive care after planned withdrawal of futile cardiorespiratory support.

Kidneys may be also be recovered from carefully selected patients who are dead on arrival at the hospital or who have died following unsuccessful resuscitation. In Spain and France most DCD kidneys are obtained from uncontrolled donors.

**Evaluation of the deceased donor**

After a deceased donor has been referred to the transplant team with a view to organ donation, the general suitability of the potential organ donor must be carefully assessed. Particular care must be taken to assess the donor from the point of view of transmissible infectious agents and malignancy. The medical history should be carefully scrutinised and evidence sought of risk factors for human immunodeficiency virus (HIV), such as intravenous drug abuse. The presence of Creutzfeldt–Jakob disease is an absolute contraindication to organ donation. Organs from HIV-infected donors should not be used for transplantation, except sometimes in recipients who are already infected by the HIV virus. Hepatitis B infection (in most countries) and active systemic sepsis, e.g. major abdominal infection, are contraindications to donation. The presence of malignancy within the past five years is usually an absolute contraindication to organ donation with the exceptions of primary tumours of the CPS, non-melanotic tumours of the skin and carcinoma in situ of the uterine cervix. If there are no general contradictions to organ donation, consideration is then given to organ-specific selection criteria.

Because of the high demand for donor organs there has been a progressive relaxation in the organ-specific selection criteria. The chronological age of the donor is less important than the physiological function of the organs under consideration for transplantation.
The organs to be donated should generally be free from primary disease. Potential kidney donors should have a reasonable urine output and relatively normal serum urea and creatinine, although acute terminal elevations are acceptable. Liver donors should not have hepatic disease, although impaired liver function tests are common in deceased donors and do not necessarily preclude donation. Heart donors should have a normal electrocardiogram and, in doubtful cases, echocardiography may be necessary. For lung donors the chest radiograph and gas exchange should be satisfactory, and bronchial aspirates should be free from fungal and bacterial infection. Elevations of blood glucose and serum amylase are not uncommon in deceased donors and do not preclude pancreas donation. The use of organs from suboptimal or 'marginal' deceased donors has increased markedly in an attempt to address the demand for transplantation. The definition of a marginal donor depends on the organs being considered for transplantation and varies between countries. In the case of kidney transplantation a marginal donor is defined in the United States as a donor age >60 years or one between the ages of 50 and 60 years with two of the following: hypertension, death from stroke and a terminal creatinine of >132 mmol/L. Organs from 'marginal donors' generally lead to less satisfactory transplant outcomes than those from standard donors.

Organ recovery from deceased donors

In DBD donors, once brainstem death has been confirmed, management of the donor is aimed at preserving the functional integrity of the organs to be recovered. Brainstem death produces profound metabolic and neuroendocrine disturbances leading to cardiovascular instability. Careful monitoring and management of fluid balance is essential. Inotropic support is given and there may be a role for the use of tri-iodothyronine (T3) and argiopressin.

Recovery of multiple organs from a DBD donor requires cooperation between the thoracic and abdominal surgical teams. A midline abdominal incision and median sternotomy is used to obtain access. After dissection of the organs to be recovered, they are perfused in situ. The heart is perfused with cold cardioplegia solution via a cannula in the ascending aorta and the lungs are perfused via a cannula in the pulmonary artery. The abdominal organs are perfused with chilled organ preservation solution via an aortic and portal cannula. Blood and perfusate are vented from the left atrial appendage and the inferior vena cavae. This produces rapid cooling of the organs, reduces their metabolic activity and preserves their viability. Additional surface cooling of the abdominal organs may be achieved by application of saline ice slush. The heart and lungs are excised followed by the liver and pancreas and then the kidneys, either en bloc or separately. The extent to which the abdominal organs are dissected prior to cold flush depends on the preference of the surgical team. Some surgeons perform minimal dissection prior to cold perfusion and complete the dissection of the abdominal organs in situ or on the back table after the organs have been removed en bloc. During recovery of the liver, care is taken to ensure that if there is an aberrant hepatic artery arising from the superior mesenteric artery it is included in the aortic patch. An adult donor liver cannot be transplanted into a child because of the size mismatch, and there are insufficient deceased paediatric donor livers available for transplantation. One solution is to undertake split liver transplantation, which was first performed by Pichlmayr in 1988. The liver from a deceased donor is split and the left lobe or left lateral segments are used for a paediatric recipient and the right lobe is used for an adult recipient (Figure 81.15).

When removing the donor kidneys care is taken to ensure that any polar renal arteries are included on an aortic patch with the renal artery (Figure 81.16). In older kidney donors with atherosclerosis the aortic segment may be too diseased to use as an arterial patch and the donor renal artery and any polar arteries are divided shortly after their origin and if necessary reconstructed prior to implantation (Figure 81.17). In the case of the pancreas, a Y graft of donor iliac artery is excised and used to reconstruct the divided splenic and superior mesenteric arteries of the graft prior to implantation (Figure 81.18).

In DCD donors there is an inevitable period of warm ischaemia (up to 45 minutes is acceptable) between the diagnosis of death (cardiorespiratory arrest) and cold perfusion of the organs. The aim during organ recovery is to minimise the period of

Figure 81.15 An adult liver may be split (according to Couinard’s segments) so that the left lateral segment (segments II and III) can be transplanted into a child and the right lobe (together with segment IV) can be transplanted into an adult. CHD, common hepatic duct; FL, falciform ligament; HA, hepatic artery (on aortic patch); IVC, inferior vena cava; LHD, left hepatic duct; LHV, left hepatic vein; LPV, left portal vein; RHA, right hepatic artery; RPV, right portal vein.

Figure 81.16 Deceased donor kidney with multiple renal arteries on an aortic patch. The aortic patch has been shortened to limit the length of the anastomosis needed when joining the donor patch to the side of the recipient external iliac artery (Medical Photography, Addenbrooke’s Hospital).

Rudolph Pichlmayr, 1932–1997, surgeon of Hannover, Germany.

Transplantation

Warm ischaemia although the approach used differs according to whether the donor is a controlled or uncontrolled DCD donor. It is important to note that only around 50 per cent of all patients considered as potential controlled DCD donors have a cardiorespiratory arrest within the period of time (usually 2 hours) considered practicable for the surgical team to stand by for organ recovery. After cardiorespiratory arrest there is an obligatory ‘hands off’ period before certification of death of at least 5 minutes before the surgical procedure for organ recovery can begin. If not already in the operating theatre, the DCD donor is transferred immediately to the operating room and the abdomen opened to allow rapid cannulation of the aorta and cold perfusion of the organs to be recovered. In the case of uncontrolled DCD donors the warm ischaemic time can be minimised by rapid insertion of a double balloon catheter introduced into the aorta via a femoral cut-down and used to cool the kidneys in situ by chilled perfusate preferably within 30 minutes of circulatory arrest (Figure 81.19). This allows time to gain consent from relatives for organ donation to proceed if it is not already available and to assemble the surgical team for organ recovery.

After removal from the donor, the organs may undergo a further flush with chilled preservation solution before they are placed in double or triple sterile bags and stored at 4°C by immersion in ice while they are transported to the recipient centre and await implantation. Once the donor organs have been excised, samples of donor spleen and mesenteric lymph nodes are obtained for confirmation of tissue type and use in the cross-match test.

Various organ preservation solutions are available for flushing organs before cold storage. They all contain impermeants to limit cell swelling, buffers to counter acidosis and electrolytes, the composition of which reflects that of intracellular rather than extracellular fluid. Commonly used preservation solutions include University of Wisconsin (UW) solution and Euro-Collins solution, but there are many others. The use of UW solution (Table 81.6) (developed by Belzer and colleagues in Wisconsin, USA) is particularly effective for liver grafts, and after perfusion with UW the liver can be stored safely for up to 24 hours. The length of time for which an organ can be stored before transplantation varies depending on the type of organ (Table 81.7). Although minimising the duration of organ storage is important for all organs, it is essential that organs from DCD donors are transplanted with the minimum possible cold storage time. Most organs for transplantation are stored by static cold storage in an ice box. However, there is a recent trend towards storing deceased donor kidneys by pulsatile machine perfusion where the kidneys are placed inside a purpose-designed perfusion machine that pumps cold preservation solution through the renal artery in an attempt to reduce ischaemic injury. Machine perfusion can be started immediately

Figure 81.18 Donor pancreas viewed from the posterior aspect after preparatory bench surgery. The duodenal component of the graft has been sutured closed proximally and distally and a Y graft of donor iliac artery used to reconstruct the divided splenic and superior mesenteric arteries. The bile duct (ligated) and portal vein are anterior and not seen in this view.

Figure 81.19 In situ perfusion of kidneys in a non-heart-beating donor (donation after cardiac death (DCD)). A double-balloon aortic catheter is introduced through a groin incision and 10–15 litres of chilled preservation solution is administered. The perfusate is vented through a Foley catheter introduced into the femoral vein.

Figure 81.17 Deceased donor kidney from elderly (>70 years) donor illustrating the technical challenges of using kidneys from marginal donors. The aorta shows severe atherosclerosis with extensive plaque formation and ulceration and is not suitable for use as an aortic patch. A lower polar artery has already been divided. The two arteries can be joined together prior to implantation or implanted separately.
Organ donation

1421

The University of Wisconsin is at Madison, WI, USA. Fokert O Belzer, 1931–1995, a surgeon of Madison, WI, USA.

Living kidney donors

Living-donor renal transplants account for around 30 per cent of the total renal transplant activity in the UK, but in some countries (notably the Scandinavian countries and the US) this figure is much higher (>50 per cent). The justification for living-donor renal transplantation is based on the shortage of deceased donor transplants and the superior results obtained. Traditionally most living-donor transplants were between genetically related individuals. However, living donor kidney transplants performed between genetically unrelated individuals also fare better than even well-matched deceased donor grafts, and this observation gave rise to a steady increase in living unrelated kidney transplantation activity, usually between spouses or partners. It is essential to ensure that in all cases of living donation the prospective donor is fully informed and is free from coercion to donate and that the risk to the donor is small.

In the UK, all living donor transplants (irrespective of whether they are genetically related or not) require prior approval by the Human Tissue Authority (HTA). An independent person (one not associated with the transplant team) approved by the HTA must provide confirmation to the HTA that the donor and recipient understand the implications of the proposed operation and that there is no evidence of coercion or financial inducement.

Live donation should proceed only after the prospective donor has undergone rigorous assessment to ensure that they are suitable. Before the donation, it is essential to perform imaging (usually magnetic resonance angiography or computed tomography-guided angiography), to delineate the anatomy of the arterial supply to the kidneys. If the left kidney has a single renal artery (10 per cent of kidneys have two or more renal arteries), it is usually chosen for transplantation because the longer left renal vein simplifies the transplant operation. The presence of multiple renal arteries does not necessarily preclude donation although implantation of living donor kidneys with multiple renal arteries may increase the chances of vascular complications developing after implantation.

Live donor nephrectomy was historically undertaken either through a loin incision and retroperitoneal approach or through a midline abdominal incision and transperitoneal approach. In most transplant units, nephrectomy is now undertaken laparoscopically (totally laparoscopic or hand-assisted). Laparoscopic nephrectomy is associated with less wound pain in the donor, allows more rapid mobilisation after surgery and reduces hospital stay. Initial concerns that kidneys removed by the laparoscopic technique may have more ureteric complications after implantation have proven unfounded. After removal from the donor the kidney is flushed immediately with chilled organ preservation solution (Figure 81.20). The mortality rate for live donation is less than 0.05 per cent, and around one-half of reported deaths are due to pulmonary embolic disease so it is essential to ensure prophylaxis to reduce deep-vein thrombosis (DVT). The major complication rate after live donor nephrectomy is <5 per cent: potential complications include haemorrhage requiring blood transfusion or surgery, infection (chest, abdomen, renal tract and wound), damage to an intra-abdominal viscus, adverse reaction to drugs and anaesthetic agents, and DVT and pulmonary embolus.

(Assuming zero warm ischaemic time and organs obtained from a non-marginal donor)

Figure 81.20 After removal from the donor kidney is flushed with chilled organ preservation solution and, if necessary, stored briefly on ice until transplanted into the recipient.
In the long term, kidney donors may be at increased risk from hypertension and donors should have their blood pressure and urine checked annually.

Around 35 per cent of potential living donor transplant recipients will be ABO blood group incompatible with their intended donor and until recently this precluded transplantation. However, there are now two potential solutions to this problem. The first is ‘paired donation’ where incompatible donor/recipient pairs exchange kidneys between pairs to allow ABO-compatible transplantation (Figure 81.21). Recruitment of more than two pairs to facilitate ‘pooled donation’ increases the likelihood of matching donors with compatible recipients and while such schemes pose considerable logistic challenges they are now operating successfully in several countries. An alternative approach is to transiently deplete ABO antibodies from potential recipients by passing their blood through special absorption columns or by performing plasmaphoresis along with administration of pretransplant immunosuppressive agents (Figure 81.22). Perhaps surprisingly, graft outcome following desensitisation is similar to that after paired donation. Both paired donation and antibody depletion strategies are also potentially applicable to recipients in whom HLA antibodies preclude transplantation from an intended living donor, but graft survival after depletion of HLA antibodies is lower than when the recipient receives a kidney from an HLA antibody-compatible donor.

**Living liver donors**

Living donor liver transplantation is now undertaken in a number of transplant centres worldwide and is relatively common practice in some countries where deceased donation is not practised for cultural or religious reasons, notably Japan and Korea. The concept was first pioneered to allow children to receive the left lobe or left lateral segment from an adult donor and has been very successful. It has now been extended to adult-to-adult live liver transplantation (Figure 81.23). The majority of such transplants require a right liver lobe to provide adequate hepatic function. For adult-to-adult live liver donation, the donor procedure has a reported mortality rate of around 0.5 per cent and a major complication rate of up to 15 per cent. One of the more common donor complications is bile leak.

**Living donors: other organs**

Occasionally, living donors have provided segments of pancreas, small bowel and lung for transplantation, but this is more controversial. In the United States, living donor combined kidney and segmental pancreas transplantation has been undertaken to treat insulin-dependent diabetics with end-stage renal disease. In occasional patients, living-donor small bowel transplantation has been performed using a small bowel graft, which comprises a length of around 1.5 m of ileum. Finally, a small number of living-donor segmental lung transplants have been performed. To provide sufficient pulmonary tissue without compromising the donor, it is necessary to use segments from two different donors for each recipient. The ethical issues raised by living donation for extrarenal organs are understandably complex.

**Resumption of function following organ transplantation**

It is crucial that following heart, lung or liver transplantation the transplanted organ resumes satisfactory function immediately. If primary non-function occurs, the only option is rapid retransplantation. After kidney, pancreas or small bowel transplantation, immediate graft function is desirable but not vital. The factors that determine the functional integrity of a transplanted organ are shown in Summary box 81.7. Kidneys

---

**Summary box 81.7**

### Factors determining organ function after transplantation

- **Donor characteristics**
  - Extremes of age
  - Presence of pre-existing damage in transplanted organ
  - Haemodynamic and metabolic instability
- **Procurement-related factors**
  - Warm ischaemic time
  - Type of preservation solution
  - Cold ischaemic time
- **Recipient-related factors**
  - Technical factors relating to implantation
  - Haemodynamic and metabolic stability
  - Immunological factors
  - Presence of drugs that impair transplant function

---

**Figure 81.21** Paired living donor kidney transplantation. Paired donation allows patients with willing but blood group-incompatible donors to be transplanted by pairing them with other incompatible donor–recipient pairs. In the example shown, the two willing donors are incompatible with their intended recipient (blood groups A to B and B to A) but by paired donation each recipient can receive an ABO-compatible kidney transplant (blood groups A to A and B to B).

**Figure 81.22** Typical desensitisation protocol for ABO or human leukocyte antigen (HLA) antibody incompatible live donor kidney transplant.
obtained from DCD donors invariably suffer a variable degree of ischaemic damage, and delayed graft function is more common (typically 50 per cent for category 3 DCD donors) than for kidneys obtained from DBD deceased donors (typically 25 per cent). Irreversible ischaemic necrosis occasionally occurs and the graft never functions adequately (primary non-function). However, graft survival results for kidneys from controlled DCD donors are similar to those obtained from DBD deceased donors. Livers obtained from DCD donors have an increased incidence of primary non-function and of biliary complications, including biliary anastomotic strictures, bile leak and ischaemic cholangiopathy.

**KIDNEY TRANSPLANTATION**

**Patient selection**

Renal transplantation is the preferred treatment for many patients with end-stage renal disease because it provides a better quality of life for them than dialysis. Transplantation releases patients from the dietary and fluid restrictions of dialysis and the physical constraints imposed by the need to dialyse. Transplantation is also more cost-effective than dialysis and improves patient survival.

In the UK, around 100 people per million of the population develop end-stage renal disease, and the incidence increases with age. The causes of end-stage renal disease are numerous and include the following:

- systemic lupus erythematosus;
- analgesic nephropathy;
- metabolic disease (oxalosis, amyloid).

Frequently, the primary cause of end-stage renal disease is uncertain. For renal transplantation, as for other types of organ transplantation, careful patient selection is essential. Before acceptance as suitable candidates on the transplant waiting list, a transplant surgeon and nephrologist should formally assess all patients. A significant number of patients are likely to be considered unsuitable for renal transplantation because of major comorbid disease, especially cardiovascular disease. In the UK, around 30–40 per cent of the dialysis population are on the waiting list for renal transplantation.

The nature of the primary renal disease does not generally affect the decision to proceed to transplantation. Many of the glomerulonephritides (especially IgA, focal segmental glomerulosclerosis, and mesangiocapillary glomerulonephritis types I and II) may recur in a kidney transplant, and sometimes can lead to early graft failure (especially focal segmental glomerulosclerosis). In the case of primary oxalosis, combined kidney and hepatic transplantation is usually undertaken to eliminate the metabolic defect and thereby prevent early graft failure from the formation of further oxalate stones.

The age of patients with end-stage renal failure accepted for dialysis has gradually risen over the last two decades, and in the UK the mean age of patients starting dialysis is around 70 years. There is no absolute upper age limit to renal transplantation, but inevitably older patients (over the age of 65 years) are less likely to be considered suitable candidates because of major cardiovascular and other comorbid disease.

A careful assessment of comorbid disease that might significantly reduce the chances of successful outcome after transplantation is essential (Summary box 81.8). Rigorous evaluation of the cardiovascular system is particularly important. Cardiovascular disease is very common in the dialysis population, especially those with diabetes, and is the major cause of death after transplantation. Before listing patients for transplantation, it is important to ensure that their urinary tract is functional and that there is no need for corrective urological surgery. Only when there is intractable renal sepsis or very large polycystic kidneys that intrude into both iliac fossae is native nephrectomy required before transplantation (Figure 81.24). Finally, the prospective transplant recipient must be deemed able to cope with the psychological consequences of transplantation and likely to comply with immunosuppressive therapy.

---

**Summary box 81.8**

**Evaluation of potential recipients for organ transplantation**

- Evaluation undertaken by appropriate multidisciplinary team including surgeon and physician
- Determine presence of comorbid disease
- Exclude malignancy and systemic sepsis
- Evaluate against organ-specific criteria for transplantation
- Determine probable ability to cope psychologically with transplant and comply with immunosuppression
- Evaluate need for any preparative surgery needed to facilitate transplantation
- Optimise recipient condition prior to transplantation
Immunosuppressive therapy impairs the protective response to both malignancy and infection. Consequently, pre-existing malignancy is an absolute contraindication and, even after curative treatment, transplantation should not usually be considered for at least three years. Similarly, the presence of active infection is a contraindication to transplantation.

**Technique of renal transplantation**

The transplant kidney is placed in the iliac fossa, in the retroperitoneal position, leaving the native kidneys in situ. After induction of general anaesthesia, a central venous line and a urinary catheter are inserted. It is helpful to distend the bladder with saline containing methylene blue to allow it to be identified with certainty prior to ureteric implantation. A curved incision is made in the lower abdomen and, after dividing the muscles of the abdominal wall, the peritoneum is swept upwards and medially to expose the iliac vessels. These are dissected free so that they can be controlled with vascular clamps. The kidney is then removed from ice and the donor renal vein is anastomosed end-to-side to the external iliac vein. The donor renal artery on a Carrel patch of donor aorta is anastomosed end-to-side to the external iliac artery (Figure 81.25a). If the donor renal artery lacks an aortic patch, as in the case of a living-donor transplant, it may be preferable to anastomose the donor artery end-to-end to the recipient internal iliac artery (Figure 81.25b). While the vascular anastomoses are being undertaken, the kidney is kept cold by application of topical ice.

Following completion of the venous and arterial anastomoses, the vascular clamps are removed and the kidney is allowed to reperfuse with blood. The ureter, which is kept reasonably short to avoid the risk of distal ischaemia, is then anastomosed to the bladder (Figure 81.26). This is achieved by direct implantation of the ureter into the dome of the bladder with a mucosa-to-mucosal anastomosis followed by closure of the muscular wall of the bladder over the ureter to create a short tunnel, the Lich–Gregoir technique. A double-J ureteric stent should be left in situ, to reduce the risk of urine leak or early obstruction, and removed after several weeks by cystoscopy. If the donor ureter is too short to reach the bladder, the native ureter can be divided...
and the distal segment anastomosed to the ureter or renal pelvis of the donor kidney. The proximal segment of the native ureter can usually be ligated and the native kidney left in situ without causing a problem. Before closing the transplant wound, it is very important to ensure that the kidney is lying in a satisfactory position without kinking or torsion of the renal vessels. In small children receiving an adult donor kidney, the abdomen is opened through a midline incision and the graft is placed intraperitoneally with anastomosis of the renal vessels to the aorta and vena cava.

**Technical complications**

**Vascular complications**

The incidence of vascular complications after renal transplantation is quite low. Renal artery thrombosis occurs in approximately 1 per cent of cases. Renal vein thrombosis is more common (up to 5 per cent of cases) and, although sometimes due to technical error, the aetiology is often uncertain. It presents during the first week after transplantation with sudden pain and swelling at the site of the graft. The diagnosis is confirmed by Doppler ultrasonography. Urgent surgical exploration is indicated, and in most cases transplant nephrectomy is required. The incidence of renal vein thrombosis can be minimised by giving low-dose heparin or aspirin prophylaxis. Renal artery stenosis usually presents late (often years) after transplantation with increasing hypertension and decreasing renal function. It may occur in up to 10 per cent of grafts and is diagnosed by angiography. Renal artery stenosis is best treated by angioplasty, but if angioplasty fails or is not technically possible then the condition can be treated successfully by open surgery and vascular reconstruction.

**Urological complications**

Urological complications occur in around 5 per cent of patients in the early post-transplant period, but their incidence can be reduced markedly by leaving a temporary ureteric stent in situ. Urinary leaks result from technical errors at the ureteric anastomosis or because of ureteric ischaemia. They present with discomfort and leakage of urine from the wound and usually require surgical intervention and reimplantation of the ureter into the bladder or anastomosis of the transplant ureter to the ipsilateral native ureter. Obstruction of the transplant ureter may occur early or late. Causes of obstruction include technical error, external pressure from a haematoma or lymphocele and ischaemic stricture. Ureteric obstruction presents with painless deterioration in graft function and is confirmed by demonstrating hydronephrosis and ureteric dilatation on ultrasound examination. Initial treatment is by percutaneous antegrade nephrostomy and insertion of a stent. Some ureteric strictures may be amenable to treatment by balloon dilatation but most are best treated by surgical intervention, reimplanting the donor ureter into the bladder or anastomosing it to the native ureter.

**Lymphocele**

Peritransplant lymphoceles are usually asymptomatic, but occasionally they become large enough to cause ureteric obstruction or oedema of the ipsilateral leg. Initial treatment is usually by ultrasound-guided percutaneous drainage. In the case of large or recurrent lymphoceles, surgical intervention may be needed to drain a persistent lymphocele into the peritoneal cavity, and this can often be achieved by an ultrasound-guided laparoscopic approach.

### Investigation of graft dysfunction

Graft dysfunction (Summary box 81.9) during the early postoperative period is a common problem. Possible causes are:

- acute tubular necrosis;
- arterial/venous thrombosis;
- urinary leak/obstruction;
- CNI toxicity;
- hyperacute/accelerated acute rejection.

#### Summary box 81.9

**Causes of allograft dysfunction**

- **Early**
  - Primary non-function (irreversible ischaemic damage)
  - Delayed function (reversible ischaemic injury)
  - Hyperacute and acute rejection
  - Arterial or venous thrombosis of the graft vessels
  - Drug toxicity (e.g. CNI toxicity)
  - Infection (e.g. CMV disease in graft)
  - Mechanical obstruction (ureter/common bile duct)

- **Late**
  - Chronic rejection
  - Arterial stenosis
  - Recurrence of original disease in graft (glomerulonephritis, hepatitis C)
  - Mechanical obstruction (ureter, common bile duct)

Delayed graft function (defined as the need for dialysis post-transplantation) as a result of acute tubular necrosis occurs in around 25 per cent of kidneys from DBD and up to 50 per cent of kidneys from DCD donors, but is uncommon (<5 per cent) following living-donor transplantation. Often, recipients produce significant volumes of urine from their native kidneys, making the diagnosis of delayed graft function more difficult. The incidence of delayed function can be minimised by optimising donor management before kidney procurement and reducing the cold ischaemia time by avoiding unnecessary delay before implantation. As a first step in the management of early graft dysfunction, the urinary catheter should be irrigated in case it is occluded by a blood clot. Hypovolaemia, if present, should be corrected with the aid of central venous pressure (CVP) monitoring. A Doppler ultrasound examination of the graft is the single most important investigation as it allows exclusion of vascular thrombosis and urinary obstruction as causes of graft dysfunction. Renal radionuclide scanning provides information on renal perfusion and excretion and may be helpful but is used infrequently. If graft dysfunction is still present after several days, it is usual to perform an ultrasound-guided needle biopsy of the kidney to ensure that graft rejection is not present and then to repeat the investigation every week or so until graft function occurs. CNI toxicity may cause graft dysfunction and it is important to monitor CNI blood levels to avoid nephrotoxicity. Acute tubular necrosis usually resolves within the first 4 weeks of transplantation, but a small number of grafts (<5 per cent) suffer primary non-function (i.e. never function).
Allograft dysfunction developing late (>1 month after transplant) may be due to:

- acute/chronic rejection;
- drug toxicity;
- urinary tract infection.

Blood levels of cyclosporine or tacrolimus are assessed to ensure that they are not unduly elevated, and ultrasound examination of the graft is performed to determine whether ureteric obstruction is present. If obstruction is detected, it is further investigated by percutaneous antegrade pyelography and treated as outlined above. If there is uncertainty about the cause of graft dysfunction, transplant biopsy should be performed to establish whether allograft rejection is present.

**Outcome after transplantation**

The results of organ transplantation (Summary box 81.10) are generally defined in terms of patient and graft survival. Patient survival after deceased donor renal transplantation is >95 per cent at one year and >85 per cent at five years. Graft survival is around 90 per cent at one year and 80 per cent at five years. Graft survival after a second transplant is only marginally worse than after a first graft. After living-related kidney transplantation, overall graft survival is around 95 per cent at one year and 85 per cent at five years. Graft survival after transplantation can also be expressed in terms of the half-life of the graft. The half-life of grafts obtained from living donors is substantially longer than that of DD grafts:

- deceased donor grafts, 13 years;
- living-unrelated grafts, 15 years;
- living-haploidentical grafts, 16 years;
- living-identical sibling grafts, 27 years.

**Summary box 81.10**

**Outcome after transplantation**

- Transplantation improves the quality and duration of life in most recipients
- Transplant outcome has improved progressively over the last two decades and continues to improve
- Improved outcome is due to better immunosuppression, organ preservation, chemoprophylaxis and technical advances
- Graft survival after kidney, liver and heart transplantation is >90 per cent at one year and >80 per cent at five years
- The results of lung and small bowel transplantation are less good
- Chronic rejection is the most common cause of graft failure after all types of solid-organ transplant
- Recurrence of the original disease necessitating transplantation may also lead to graft failure
- Death with a functioning transplant from cardiovascular disease is relatively common
- Up-to-date transplant outcomes for the different organs can be found at the online national and international transplant databases (see end of chapter for website addresses)

If a kidney transplant fails late after transplantation, the graft can often be left in situ and immunosuppression stopped, but transplant nephrectomy may be indicated if the graft is causing symptoms. The operation is undertaken via the original wound, but the kidney is dissected free from the renal capsule and delivered into the wound. The renal vessels are then ligated and divided, leaving behind the original vascular anastomosis.

In addition to graft survival, it is important to consider the extent to which transplantation improves the physical and mental well-being of the patient and allows them to lead a satisfactory social life. In the case of kidney, as in other types of solid organ transplant, successful transplantation undoubtedly leads to a substantial improvement in quality of life. However, although some recipients return to a normal or near-normal life, others fare much less well and, for the group overall, the quality of life after transplantation falls short of that seen in normal healthy individuals. Renal transplantation is best regarded, therefore, as an effective form of therapy rather than a complete cure.

**PANCREAS TRANSPLANTATION**

Successful pancreas transplantation restores normal control of glucose metabolism and obviates the need for insulin therapy in patients with diabetes mellitus. Improved control of blood glucose levels in diabetes reduces the progression of secondary complications such as retinopathy, peripheral vascular disease and nephropathy. However, in considering the indications for pancreas transplantation, these advantages have to be weighed carefully against the risks posed by both the transplant procedure itself and the immunosuppressive therapy required to prevent graft rejection. For most patients with diabetes, the additional risks associated with pancreas transplantation and immunosuppression are such that the operation can be justified only when kidney transplantation for diabetic nephropathy is also being undertaken. The only additional risks of pancreas transplantation in such patients relate to the transplant operation itself. In the United States, around one-half of all diabetic patients undergoing kidney transplantation also receive a pancreas transplant. In most cases, the kidney and pancreas are obtained from the same donor, so-called simultaneous pancreas and kidney (SPK) transplantation. Pancreas transplantation is sometimes performed in patients who have already undergone successful kidney transplantation, pancreas after kidney (PAK) transplantation. Occasionally, pancreas transplantation alone (PTA) can be justified to treat life-threatening diabetic complications such as hypoglycaemic unawareness.

Careful patient selection is essential to avoid excessive mortality and morbidity. The procedure is usually reserved for those patients with type 1 diabetes who are relatively young (under the age of 55 years) and do not have advanced coronary artery disease or peripheral vascular disease. Investigation of the heart’s response to stress, either using echocardiography or nuclear medicine imaging is mandatory.

**Surgical technique**

The whole pancreas gland together with a segment of duodenum is transplanted, essentially as pioneered by Lillehei in 1966. Segmental pancreas transplantation is performed only occasionally. SPK transplantation is usually performed through a midline incision (Figure 81.27). The pancreas graft is placed intraperitoneally in the pelvis, usually on the right, and the
kidney graft is placed on the left side. The donor vessels of the pancreas graft are anastomosed to the recipient iliac vessels and the exocrine secretions are most commonly dealt with by anastomosing the graft duodenum to the small bowel (enteric drainage) often via a roux-en-Y loop although the duodenum may sometimes be anastomosed to the bladder (urinary drainage). The pancreas graft functions immediately after revascularisation, although supplementary insulin may be required for a few days. Technical complications usually occur early and include vascular thrombosis of the graft (5 per cent) and duodenal anastomotic leaks. Wound infection occurs in up to 10 per cent of patients, and intra-abdominal infection is relatively common. The specific complications of enteric drainage include intra-abdominal sepsis and adhesive small intestinal obstruction. Bladder drainage of the exocrine pancreas may result in the following complications:

- bladder/duodenal anastomotic leaks;
- cystitis (owing to effect of pancreatic enzymes);
- urethritis/urethral stenosis;
- reflux pancreatitis;
- urinary tract infection;
- haematuria;
- metabolic acidosis (due to loss of bicarbonate in the urine).

Urinary drainage of the pancreas has the advantage that urinary amylase levels can be used to monitor for graft rejection. However, after bladder drainage, urinary complications are common, and in around 20 per cent of cases their severity necessitates conversion to enteric drainage. Most centres now prefer primary enteric drainage after SPK transplantation. Acute rejection after SPK transplantation is relatively common (10–20 per cent) and if detected early responds to treatment with steroids. Since it usually involves both the kidney and pancreas graft, serum creatinine can be used as a surrogate marker for pancreas graft rejection. Serum lipase and amylase levels are useful indications of pancreas graft inflammation of which acute rejection is one cause. Urinary drainage has the advantage, after PTA and PAK transplantation, of allowing pancreas graft rejection to be monitored by serial measurement of urinary amylase. A fall in urinary amylase is indicative of acute rejection. Elevation of blood glucose level is a late feature of acute rejection and often indicates the process is beyond reversal.

**Results of pancreas transplantation**

The principal aim of pancreas transplantation is to prolong life in diabetic patients who otherwise have a high mortality at ten years after receiving a kidney transplant alone. It also provides freedom from insulin treatment and improves quality of life.

The results of pancreas transplantation have improved significantly over the last decade. After SPK transplantation, the one-year patient survival rate is greater than 95 per cent and the one-year graft survival rates for pancreas and kidney grafts are 85 and 95 per cent, respectively. Most deaths are due to cardiovascular complications or overwhelming infection. Patient and kidney graft survival after SPK transplantation in patients with diabetic nephropathy is at least as good as after kidney transplant alone in this group. The results of PTA are not as good as after SPK transplantation (one-year pancreas graft survival 75 per cent) because acute rejection is more difficult to monitor in the absence of a kidney allograft.

**Transplantation of isolated pancreatic islets**

Treatment of diabetes by transplantation of isolated islets of Langerhans is a more attractive concept than vascularised pancreas transplantation because major surgery and the potential complications of transplanting exocrine pancreas are avoided. Pancreatic islets for transplantation are obtained by mechanically disrupting the pancreas after injection of collagenase into the pancreatic duct. The islets are then purified from the dispersed tissue by density-gradient centrifugation and can be delivered into the recipient liver (the preferred site for transplantation) by injection into the portal vein. Until recently, human islet transplantation had been performed intermittently and with very disappointing results. However, in 2000, Shapiro and colleagues in Edmonton, Canada, reported success with islet transplantation in seven patients with type I diabetes. Sequential islet transplantation from two or three donor pancreas glands was required to produce insulin independence, and although the long-term success is less than initially hoped for, some patients remained free from exogenous insulin and other units are now undertaking islet transplantation with variable results.

As an alternative to preventing islet rejection through immuno-suppressive therapy, attempts have been made to protect isolated islet cells from rejection by encapsulating them inside semipermeable membranes. The protective membranes are designed with a pore size that allows insulin to pass through but prevents antibodies and leukocytes from reaching the islets, thereby avoiding the need for immunosuppressive therapy. A major attraction of this approach is that islets isolated from animals can be used and biosartificial pancreas grafts containing xenogeneic islets are currently under evaluation.

**LIVER TRANSPLANTATION**

Starzl first attempted liver transplantation in 1963 and, by 1967, had achieved prolonged survival. The first liver transplant

Richard Lillehei, surgeon, the University of Minnesota, Minneapolis, MI, USA.
Paul Langerhans, 1847–1888, Professor of Pathological Anatomy, Freiberg, Germany, described the islets in 1869.
Andrew Mark James Shapiro, Chairman of Clinical Research in Transplantation, CHRI/Wyeth Canad, Edmonton, Alberta, Canada.
performed outside the US was performed in Cambridge, UK by Calne in 1968. Throughout the 1970s, liver transplantation remained a hazardous procedure that frequently failed. However, since then, the results have progressively improved as a result of better patient selection, improved immunosuppression and chemoprophylaxis, better organ preservation, refinements in the operative technique, and advances in peri- and postoperative management.

**Indications and patient selection**

The indications for liver transplantation fall into four groups:

1. cirrhosis;
2. acute fulminant liver failure;
3. metabolic liver disease;
4. primary hepatic malignancy.

The most common indication for transplantation is chronic liver failure. In adults the most common causes are alcoholic liver disease, viral liver disease (hepatitis C in Europe and the US and hepatitis B in some other countries), non-alcoholic steatohepatitis, primary biliary cirrhosis and sclerosing cholangitis. In children, who account for around 10–15 per cent of all liver transplants, biliary atresia is the most common indication for transplantation. Acute fulminant liver failure requiring transplantation on an urgent basis accounts for approximately 10 per cent of liver transplant activity and is usually viral or drug induced (e.g. paracetamol overdose in the UK). There are a variety of metabolic diseases for which transplantation offers the prospect of cure. These include Wilson's disease, oxalosis and familial amyloid polyneuropathy. Primary hepatic malignancy is more common in patients with cirrhosis, especially virally induced disease, and may be best treated by transplantation because the field changes in the cirrhotic liver predispose to further primary malignancies. Cholangiocarcinoma has a high recurrence rate and is seldom an indication for liver transplantation.

**Technique of liver transplantation**

A transverse abdominal incision with a midline extension is usually made and the diseased liver is mobilised (Figure 81.28). Because of portal hypertension, the recipient hepatectomy is often the most difficult part of the operation, especially if there has been previous upper abdominal surgery. The common bile duct is divided, as is the hepatic artery. The inferior vena cava is clamped and divided above and below the liver, and the portal vein is clamped and divided, allowing the recipient liver to be removed. Occlusion of the vena cava and portal vein results in a reduction in cardiac output and may necessitate the use of venovenous bypass. The bypass circuit delivers blood from the inferior vena cava and/or portal vein and back to the heart via a cannula inserted into the internal jugular vein. After placing the donor liver in position, the supra- and infrahepatic caval anastomoses are performed. The portal vein and the hepatic arterial anastomoses are then completed and the graft is reperfused. Finally, biliary drainage is re-established usually by a duct-to-duct anastomosis (without the use of a T-tube). It may be necessary, for example in recipients with biliary atresia or sclerosing cholangitis, to reconstruct the biliary drainage by a bile duct to Roux loop anastomosis. An alternative caval preservation technique of liver transplantation allows the recipient liver to be removed without cross-clamping the vena cava and the donor liver to be implanted using a 'piggyback' technique onto the recipient hepatic veins or using a side-to-side cavocavopasty.

Many patients undergoing liver transplantation are extremely ill, and the surgery involved can be very technically demanding. Optimal perioperative management is crucial to a successful outcome and presents a major challenge. Blood loss during and after the transplant procedure can be very considerable, and management of coagulopathy is particularly important. Coagulation is assessed repeatedly throughout the transplant period and corrected with appropriate clotting factors. Many centres routinely use a thromboelastography to perform dynamic assessment of coagulation (Figure 81.29). In the most widely used system (rotational thromboelastography) this involves placing a blood sample in a small cuvette and then inserting a sensor pin that is subjected to rotational torsion and as clot between the cuvette and the pin forms, the resulting signal is displayed graphically and indicates the speed and strength of clot. Various modifications can be made to the test conditions to maximise the information provided.

![Figure 81.28](image1)  
**Figure 81.28** (a) Incision used for liver transplantation. (b) Completed implantation. The anastomoses, in order of performance, are: (1) suprahepatic cava; (2) infrahepatic cava; (3) portal vein; (4) hepatic artery; (5) bile duct.

*Samuel Alexander Kinnier Wilson, 1878–1936, Professor of Neurology, King’s College Hospital, London, UK, described this condition in 1912.*
Technical complications

Haemorrhage
Meticulous haemostasis during the transplant operation is important in order to minimise the risk of early haemorrhage. It may be necessary, occasionally, to pack the peritransplant area for 2–3 days to achieve adequate haemostasis when there is diffuse oozing despite correction of coagulopathy. Evacuation of extensive perihepatic haematoma may be required to avoid secondary infection.

Vascular complications
Heaptic artery thrombosis may occur spontaneously or as a result of acute rejection and is more common in paediatric recipients and in adults with primary sclerosing cholangitis. It may present as a rise in serum transaminase levels, unexplained fever or bile leak. Doppler ultrasonography or angiography is used to confirm the diagnosis, and urgent retransplantation is usually required. Portal vein thrombosis is rare and presents with the features of portal hypertension.

Biliary complications
Biliary leaks are now relatively uncommon and biliary stenosis is the more common problem. It usually occurs within the first few months of transplantation and is managed by endoscopic dilatation and stenting or by surgical correction.

Outcome after liver transplantation
The outcome after liver transplantation depends on the underlying liver disease and the best results are seen in patients with chronic liver disease (Figure 81.30). Patients undergoing transplantation as a result of acute liver failure have a higher mortality in the early post-transplant period because of multiorgan failure, but those who make a satisfactory recovery have very good long-term liver allograft survival. Conversely, patients transplanted for tumour have a very good early outcome but ultimately fare much less well because of recurrent malignancy. Patients receiving a liver transplantation following hepatitis B or hepatitis C infection may develop graft failure as a result of recurrent viral disease. However, the availability of improved antiviral therapy has largely eliminated this problem in recipients with hepatitis B infection.

SMALL BOWEL TRANSPLANTATION
Progress in small bowel transplantation has lagged behind that of other types of organ transplantation but it is now a well-established therapy for highly selected recipients. Intestinal transplants stimulate a particularly strong graft rejection response, probably because the small intestine contains very large amounts of lymphoid tissue. Moreover, ischaemia and rejection increase intestinal permeability and allow translocation of bacteria from the lumen of the bowel. Added to this, the operation is often complex and is made technically difficult because of repeated previous abdominal surgery. Consequently, graft rejection and infection remain major problems after small bowel transplantation and the results obtained are inferior to those seen after other types of organ transplantation. Small bowel transplantation is a treatment option for patients with intestinal failure to an extent that long-term parenteral nutrition is required. Intestinal failure may result from short bowel syndrome after resection of the intestine or from intestinal dysfunction. Conditions that may give rise to intestinal failure include the following:

- intestinal atresia;
- necrotising enterocolitis;
- volvulus;
- disorders of motility;
- mesenteric infarction;
- Crohn’s disease;
- trauma;
- desmoids tumours.

Because of the substantial risks associated with small bowel transplantation, the procedure is only considered for those patients in whom long-term total parenteral nutrition (TPN) has failed, usually because venous access has become impracticable or because of frequent life-threatening line sepsis. The need for small bowel transplantation is estimated at around 0.5–1.0 patients per million of the population, and around 50 per cent of cases are children.

Small bowel transplantation may be carried out as an isolated procedure, performed together with a liver transplant or undertaken as a component of a multivisceral transplant. When possible, isolated small bowel transplantation is undertaken because patient survival is higher.

A small bowel transplant from a deceased donor comprises the entire small bowel, and may include the ascending colon in the graft. The superior mesenteric artery of the graft (with an aortic patch) is anastomosed to the recipient aorta, and the superior mesenteric vein is anastomosed to the inferior vena cava or to the side of the portal vein. The proximal end of the small bowel graft is anastomosed to the recipient jejunum or duodenum. The distal end of the graft is anastomosed to the side of the colon (with a loop ileostomy) or is fashioned as an
end ileostomy. A gastrostomy tube (to overcome delayed gastric emptying) and a feeding jejunostomy tube are inserted.

About one-half of all patients who require small bowel transplantation have cholestatic liver disease secondary to TPN and require combined liver and small bowel transplantation. Cholestatic liver disease due to TPN is especially common in children. When combined liver and small bowel transplantation is carried out, the two grafts are transplanted en bloc. The donor aorta is fashioned into a conduit including the superior mesenteric and coeliac arteries and anastomosed to the recipient aorta. The portal vein anastomosis is as for isolated liver transplantation (Figure 81.31).

Multivisceral or 'cluster' transplants may be necessary in the case of large desmoid tumours when excision of both the small bowel and adjacent organs is required, when there has been extensive thrombosis of the splanchnic vessels and for generalised disorders of gastrointestinal motility.

The one-year graft survival rate after small bowel transplantation is about 70 per cent for both isolated small bowel transplantation and for combined liver and small bowel transplantation. After three years, the graft survival rate is around 50 per cent. As already noted, however, patient survival is better after isolated small bowel transplantation than after combined liver and small bowel transplantation, when loss of the graft usually equates with death of the recipient. Most of the mortality after small bowel transplantation is due to sepsis and multiorgan failure. The risk of infection after small bowel transplantation is heightened by the additional requirements for immunosuppression in order to control graft rejection. This accounts for the relatively high incidence of lymphoproliferative disease (around 10 per cent) observed in patients who have undergone small bowel transplantation. Because of the large amount of donor lymphoid tissue transplanted, GVHD may be an added complication. Despite the hazards, small bowel transplantation offers patients with intestinal failure a chance to lead an active life free from the constraints of long-term nutritional support.

Figure 81.31 Combined liver and small bowel transplant in an adult shortly after reperfusion of the grafts. The small bowel is well perfused via the superior mesenteric artery anastomosed to the aorta on a patch along with the coeliac axis, and the venous blood drains into the portal vein via the superior mesenteric vein.

THORACIC ORGAN TRANSPLANTATION

Heart transplantation

Dr Christian Barnard performed the first human heart transplant in Cape Town, South Africa, in 1967. The operation was based on the experimental work of Lower and Shumway in Stanford, and Shumway subsequently went on to pioneer successful cardiac transplantation in the clinic. Heart transplantation is now considered an effective treatment for selected patients with end-stage cardiac failure. The most common indications for heart transplantation are ischaemic heart disease and idiopathic cardiomyopathy, but other indications include valvular heart disease, myocarditis and congenital heart disease.

Transplantation is considered only in patients with end-stage heart disease that has failed to respond to all other conventional therapy and when predicted survival without transplantation is only 6–12 months. Transplantation is usually limited to patients under the age of 65 years who do not have irreversible damage to other organ systems. The preoperative assessment is rigorous, and measurement of pulmonary vascular resistance is mandatory because when it is raised the perioperative mortality is high.

Technique of heart transplantation

A median sternotomy is performed and the patient is given systemic heparin, placed on cardiopulmonary bypass and cooled to 29°C. After cross-clamping the aorta, the recipient heart is excised at the mid-atrial level. The donor heart is then prepared and the left atrium is opened by making incisions (Figure 81.32 in the posterior wall, between the orifices of the pulmonary veins, to create an atrial cuff. The left and then right atrial

Figure 81.32 Recipient cardiectomy. After median sternotomy, the recipient heart is excised, leaving behind cuffs of right and left atria. The diseased recipient heart is excised, leaving behind cuffs of right and left atria. PA, pulmonary artery; IPV/SPV, inferior/superior pulmonary veins; LA, left atrium (courtesy of J Dunning).
anastomoses are performed and the pulmonary and aortic arterial anastomoses are then completed (Figure 81.33). The patient is then rewarmed and weaned from cardiopulmonary bypass. Occasionally, heterotopic cardiac transplantation is undertaken, when the donor heart is placed adjacent to and augments the recipient’s own heart.

**Heart-lung, single-lung and double-lung transplantations**

Pulmonary transplantation became a clinical reality when Dr Bruce Reitz performed the first successful combined heart–lungs transplant in 1981. Combined heart–lungs transplantation is still sometimes performed, usually in patients with pulmonary vascular disease in whom there is cardiac dysfunction due to congenital (e.g. Eisenmenger syndrome, in which the left-to-right shunt is reversed owing to pulmonary hypertension) or acquired cardiac dysfunction. For most patients with end-stage pulmonary disease, however, single- or double-lung transplantation has now replaced heart–lungs transplantation. Lung transplantation is more economical in terms of organ use, although if heart–lungs transplantation is undertaken for isolated respiratory disease, the healthy native heart can be used for transplantation, the so-called ‘domino procedure’. Heart–lungs transplantation is performed through a median sternotomy, taking particular care to avoid injury to the phrenic, vagus and recurrent laryngeal nerves during excision of the recipient heart and lungs. The recipient right atrium and aorta are divided as for orthotopic cardiac transplantation and the donor heart–lungs block readied for implantation, incising the right atrium from the divided inferior vena cava. An end-to-end tracheal anastomosis is performed and the right atrial and aortic anastomoses are performed as for cardiac transplantation.

Single- and double-lung transplantation are effective therapies for selected patients with end-stage chronic lung disease, in whom declining lung function limits life expectancy despite optimal medical therapy. Common indications are pulmonary fibrosis, pulmonary hypertension, emphysema and cystic fibrosis. Single-lung transplantation can be performed for pulmonary fibrosis. Single-lung transplantation is performed through a posterolateral thoracotomy and double-lung transplantation through a bilateral thoracotomy or median sternotomy. During lung transplantation, the donor pulmonary veins on a left atrial cuff are anastomosed to the recipient left atrium. Next, the bronchial anastomosis and the pulmonary arterial anastomosis are completed. Cardiopulmonary bypass is usually required if pulmonary hypertension is present. Dehiscence of the airway anastomosis used to be common after heart–lungs and lung transplantation, but improvements in organ preservation and surgical technique have dramatically reduced the incidence of this often fatal complication to <5 per cent. Late airway stenosis at the bronchial anastomosis due to ischaemia occurs in around 10 per cent of bronchial anastomoses and is treated by dilatation.

**Outcome after thoracic organ transplantation**

The one- and five-year graft survival rates after heart transplantation are around 85 and 70 per cent, respectively. The results after heart–lungs and lung transplantation are less good, with one-year graft survival rates of around 75 per cent and five-year survival rates of around 50 per cent.

**FUTURE PROSPECTS**

The two major problems in organ transplantation are:

1. chronic graft rejection and the side effects of non-specific immunosuppression;
2. the shortage of organs for transplantation.

New immunosuppressive agents that have fewer or different agent-specific side effects than existing therapy are likely to enter clinical practice and there is continuing research into the development of non-invasive biomarkers (in urine or blood) that will allow early diagnosis of graft rejection. A long-standing goal in organ transplantation has been the development of strategies for inducing specific immunological tolerance (Summary box 81.11). Transplantation tolerance would eliminate the need for long-term non-specific immunosuppressive agents, leaving the immune system intact for defence against infection. It has long been possible to induce transplant tolerance in experimental animals with a variety of preconditioning regimens that often involve pre-treatment schedules using donor bone marrow cells or donor antigen. So far, however, there is no clinically applicable strategy for inducing transplant tolerance.

**Summary box 81.11**

**Future developments in transplantation**

- Novel immunosuppressive agents
- Non-invasive biomarkers for early diagnosis of graft rejection
- Donor-specific immunological tolerance
- Xenotransplantation
- Stem cell medicine and tissue engineering
The demand for human organs for transplantation is so great that deceased donors cannot ever satisfy it. Many consider that the solution is to perfect xenotransplantation, and there is general agreement that the pig is the most suitable source of xenogeneic organs. However, all humans have preformed antibodies directed against carbohydrate antigens expressed by pig organs, and these cause hyperacute rejection. The dominant carbohydrate antigen responsible is gal-1, 3-αgal. Progress has been made towards circumventing hyperacute xenograft rejection and pigs that have been genetically engineered not to express the gal-1, 3-αgal antigen have been produced. However, organs from genetically modified pigs are still rejected within a few weeks by primates, despite the use of potent immunosuppressive agents. In addition to the complex immunological problems posed by xenotransplantation, there is a risk that pig organs may transmit infectious agents, and there is particular concern about the risks posed by porcine endogenous retrovirus (PERV). Lastly, there are unanswered questions regarding the extent to which pig organs are able to fulfil the physiological demands required of them after transplantation into a human.

Finally, looking to the future, there is optimism that human pluripotent stem cells may ultimately provide a source of tissue transplants for treating a wide range of diseases. Attempts are now under way to define the cell signals needed to guide human embryonic and adult-induced pluripotent stem cells to differentiate in vitro into functional tissue of the desired cell type. These include insulin-producing cells, cardiac myocytes and neuronal tissue. Although cell transplantation is the initial goal, by combining the developments in stem cell medicine with those taking place in tissue engineering and biomaterials it may one day be possible to engineer more complex vascularised grafts for transplantation.

**FURTHER READING**

This is a list of some of the instruments used in open (as opposed to minimal access surgery) ‘general surgery’ with information on how they are used and about the people associated with them. It is hoped that this information will help the general surgical trainee answer questions on operative surgery in postgraduate examinations.

**Langenbeck retractor.** This small general purpose retractor is useful for holding open wounds, as in an open appendicectomy. They are often used in pairs (one in each of the assistant’s hands). They stay in position best if the handles are lifted slightly so that the tips lock in under the fascia. The width of the lip of the retractors varies. Bernhard Rudolf Konrad von Langenbeck (1810–1887) was Professor of Surgery successively at Kiel and Berlin, Germany. He performed the first internal fixation of a femoral neck fracture in 1850.

**Morris retractor.** This is a big retractor which is useful for giving maximum exposure in large incisions such as those used in the abdomen. It can be used to improve visibility on one side of an incision (by pulling firmly in that direction); so is valuable during the initial phase of a laparotomy. Sir Henry Morris (1844–1926) was a surgeon at the Middlesex Hospital, London, UK.

**Deaver retractor.** This retractor is specifically designed for holding the liver up out of the way during a cholecystectomy. It needs to be used carefully to avoid damaging the liver. Some surgeons protect the liver with an abdominal pack before placing the blade on top. John Blair Deaver (1855–1931) was Professor of Surgery at the University of Pennsylvania Medical School, Philadelphia, PA, USA. He also described a paramedian incision for appendicectomy.

**Dyball retractor.** Used in major abdominal surgery to retract deeper parts of the abdominal wall or the bladder or the uterus while operating on the rectum and entering the rectovesical or rectouterine pouch. It has a lip at the bottom of the blade to prevent slippage. Care should be taken if it is used to retract the liver in operations in the region of the right upper quadrant as it may damage the liver parenchyma. Brennan Dyball was a distinguished West Country surgeon from Exeter. He also excelled as a carpenter and motor mechanic. He died in 1934 at the age of 62 leaving a great professional legacy to the Royal Devon and Exeter Hospital.

**Joll retractor.** This is a self-retaining retractor used in thyroid surgery. After making the collar incision and raising the lower and upper flaps fully, this retractor is then inserted. The two clips on the upper and lower edges are attached to the skin preferably with a swab over the skin edge. The central segment is then unscrewed to separate the two edges to obtain full exposure. Cecil Augustus Joll was a surgeon in London who first qualified as a dentist. He was regarded as ‘a brilliant technician and an extraordinarily versatile surgeon’ who operated on conditions ‘from knees to necks and stomach to perineum’. A keen ornithologist, he was a connoisseur of all things good – furniture, pottery, food, wines and cigars. He died in 1945 at the age of 59.
**Goligher retractor.** This is a self-retaining retractor used in operations on the sigmoid colon and rectum, such as anterior resection and upper end of abdominoperineal resection. Once the abdomen has been opened and laparotomy performed, the patient is placed head down and all the small bowel is packed to the upper end of the abdomen. The retractor is then inserted with the side blades to separate the edges of the abdominal wall. The central blade is then inserted to keep the small bowel well tucked away from the operation site. All three blades come in different widths to fit in with the patient’s build. John Cedric Goligher (1912–1998), Ulsterman by birth, Professor of Surgery at Leeds, his contributions to colorectal surgery in the world have been legendary. His operating theatres at Leeds General Infirmary ‘have been the Mecca for surgeons from all over the world’. His book, *Surgery of the Anus, Rectum and Colon*, was regarded as the ultimate authority on the subject and had five editions.

**St Mark’s perineal retractor.** This is used for the perineal part of an abdominoperineal resection. After making the perineal incision and adequate dissection of the perineal wound, the retractor is inserted. As the dissection proceeds, the retractor has to be repositioned. The pointed ends are directed towards the front. St Mark’s Hospital, Harrow, UK, is recognised as a national and international referral centre for intestinal and colorectal disorders. It was founded in a small room in No. 11 Aldersgate Street. Established in 1854 on City Road in Hackney as St Mark’s Hospital for Fistula and other Diseases of the Rectum. It was so named as it was opened on St Mark’s Day, 25 April. In 1994, it moved to its present site in Harrow.

**Travers retractor.** This is a self-retaining retractor used for intermediate-type operations, such as herniorrhaphy, groin dissection for varicose veins and femoral embolectomy. It retracts skin and subcutaneous tissues; as the incision is deepened, the retractor has to be repositioned. If used incorrectly, it can traumatised the skin. For longer incisions, two such retractors may be used, one at each end of the incision for good exposure. Benjamin Travers (1783–1858) was a surgeon to the London Infirmary for Disease of the Eye (now Moorfields Ophthalmic Hospital). He is regarded as the first general hospital surgeon in England to devote himself especially to disease of the eye. He later became surgeon to St Thomas’s Hospital and Vice-President and President of Royal College of Surgeons of England and a Fellow of the Royal Society. As an operator, he was regarded as clumsy and nervous. He had ‘exquisite polish of manners, took off his hat and acknowledged salutes more elegantly than any contemporary dandy’.

**West retractor.** Used in a similar manner to the Travers retractor, this is ideal for minor procedures under local anaesthetic where the surgeon is operating without an assistant, e.g. lymph node biopsy, temporal artery biopsy. After making the incision and undermining the edges, the retractor is then inserted and the jaws are prised open gently. Charles Ernest West (1873–1951) ‘aural surgeon’ of St Bartholomew’s Hospital is credited with devising this retractor. It is possible that he got the idea from Franz Weitlaner, an Austrian physician who published the first description of his retractor in the *Vienna Clinical Review* in 1905. He became known as ‘the great spreader of surgery’. It would be safe to presume that the present retractor is West’s modification of Weitlaner’s spreader.

**Czerny retractor.** This is a double-ended retractor used to retract wound edges for intermediate-type procedures. One end has a blade with a lip which helps to retract without the edge slipping. The other end has two prongs and helps to retract the ends of an incision. When using it, a slight upward tilt gives a better exposure. It is used where a Langenbeck retractor can also be used, but the lip here is broader making it more versatile. Vincenz Czerny (1842–1915) was Professor of Surgery at Freiberg and Heidelberg in Germany. He was a disciple of Theodor Billroth. He was the originator of the concept of multidisciplinary management in cancer.

**McIndoe scissors.** Are used by surgeons to perform dissection respecting anatomical planes. The closed blades are inserted into a fascial plane, and then gently opened. The tissue to be divided can then be seen clearly and divided without risk of damage to vital structures. Sir Archibald Hector McIndoe (1900–1960) was a plastic surgeon at St Bartholomew’s Hospital, London, and the Queen Victoria Hospital, East Grinstead, UK. He was born in New Zealand (cousin of Harold Gillies) and became a consultant plastic surgeon to the RAF during the Second World War. He supervised the rehabilitation of badly disfigured airmen who later formed the Guinea Pig Club.
DeBakey forceps allow the surgeon to grasp tissues firmly while minimising damage to the tissue held in the jaws of the forceps. They are useful for holding vessel walls in vascular surgery. Michael Ellis DeBakey (1908–2008) was Professor of Surgery at Baylor University College of Medicine, Houston, TX, USA. He was the first to successfully implant an artificial heart; he also performed the first successful carotid endarterectomy.

Gillies forceps have teeth and are ideal for holding tough tissues, such as skin. Sir Harold Gillies (1882–1960) was a plastic surgeon at St Bartholomew’s Hospital, London, UK. He was born in New Zealand (cousin of Archibald McIndoe) and became one of the founders of British plastic surgery. He originated the tubed pedicle flap.

Adson forceps are non-toothed, and so are ideal for holding delicate tissues, such as bowel. Alfred Washington Adson (1887–1951) was Professor of Neurosurgery at the Mayo Clinic, Rochester, MN, USA. He was one of the first to use sympathectomy for the treatment of hypertension, and cervical sympatheticotomy for Raynaud’s syndrome.

Allis forceps are used to hold soft tissues for a long period while minimising tissue damage. Using the ratchet they can be locked on to tissue, such as bowel, and can be used to provide gentle traction. Oscar Huntington Allis (1836–1921) was a surgeon at the Presbyterian Hospital, Philadelphia, PA, USA.

Babcock forceps. This is used to grasp any part of the bowel. The jaws are atraumatic and cause minimal tissue damage. Used commonly in appendicectomy to grasp the appendix and deliver it out of the wound. Care is taken when using it not to perforate the inflamed appendix. William Wayne Babcock (1872–1963), Professor and Head of the Department of Surgery at the Temple University School of Medicine, Philadelphia for 40 years. ‘He was the inventor of the acorn-shaped vein stripper, introduced the alloy steel wire sutures, wire mesh in hernia repairs, and zinc chloride in the treatment of osteomyelitic sinus’.

Spencer Wells forceps. These were one of the first ratchet forceps ever designed and are still very useful. They are often used in pairs for clamping an artery before dividing it. The cut ends of the artery are then tied off, and the forceps removed (carefully!). Sir Thomas Spencer Wells (1818–1897) was a surgeon at the Samaritan Free Hospital for Women and Children, London, UK. He was one of the earliest surgeons to make use of anaesthetics in operation.

Kocher dissector. This is used during a thyroidectomy to dissect the upper pole of the thyroid. The instrument is blunt and therefore the surgeon is highly unlikely to inadvertently damage the superior thyroid artery or the external laryngeal nerve. It is used to dissect the superior pedicle, the superior thyroid artery. Once it has been isolated, the dissector is pushed under the pedicle. A tie is then put through the eye of the dissector which at this stage doubles up as an aneurysm needle. The pedicle is thus tied three times as close to the gland as possible. With the dissector under the tied pedicle, a fine knife is now used to cut leaving two ties in the patient. The presence of the dissector under the pedicle prevents any damage to the underlying structures. Emil Theodor Kocher (1841–1917), Professor of Surgery at Berne, Switzerland, was awarded the Nobel Prize for Physiology or Medicine in 1909 for his work on the thyroid. The first surgeon to be a Nobel Laureate.

ACKNOWLEDGEMENTS

With thanks to Steven Kerr, Assistant Librarian, Royal College of Surgeons of Edinburgh.
Bailey & Love’s Short Practice of Surgery remains one of the world’s pre-eminent medical textbooks, beloved by generations of surgeons, with lifetime sales in excess of one million copies. Under the guidance of the eminent editors, the expert team of contributors have revised and updated the material throughout while retaining those features praised in previous editions.

The content is sub-divided into parts for ease of reference. Sections devoted to the underlying principles of surgical practice, investigation and diagnosis, and pre-operative care are followed by chapters covering all aspects of surgical trauma. The remainder of the book considers each of the surgical specialties in turn, from elective orthopaedics through skin, head and neck, breast and endocrine, cardiothoracic and vascular, abdominal and genitourinary to transplantation.

Key features:

- **Authoritative** – emphasises the importance of effective clinical examination and soundly based surgical principles while taking account throughout of the latest developments in surgical practice
- **Current** – text and illustrations fully revised with brand new chapters on patient safety, day care surgery and bariatric surgery
- **Readable** – preserves the clear, direct writing style, uncluttered by technical jargon, that has proved so popular in previous editions
- **User-friendly** – numerous photographs, explanatory line diagrams, learning objectives, summary boxes, biographical footnotes and memorable anecdotes support and enhance the textual descriptions

The 26th edition of Bailey & Love retains a wide appeal among all those studying surgery, from undergraduate medical students to those in preparation for their postgraduate surgical examinations. In addition, its high standing and reputation for unambiguous advice continue to make it the first point of reference for many practising surgeons.

About the editors:

**Norman S. Williams** MS FRCS FMedSci is Professor of Surgery and Director of Surgical Innovation, Barts and the London School of Medicine and Dentistry, Queen Mary, University of London and President, The Royal College of Surgeons of England, London, UK

**Christopher J.K. Bulstrode** MCh FRCS(T&O) is Emeritus Professor, University of Oxford, Oxford, UK

**P. Ronan O’Connell** MD FRCSI FRCPS Glas is Head, Surgery and Surgical Specialties, UCD School of Medicine and Medical Sciences; Consultant Surgeon, St Vincent’s University Hospital, Dublin, Ireland

This is a specially priced edition, published exclusively for the benefit of students living in newly industrialized countries and those with a developing economy. If you have made your purchase in North America, Europe (excluding Eastern Europe), Japan, Australia or New Zealand, this book is being made available in an unlawful way, without the approval of the Publisher or Authors.
